Ethnobotany of Alaska: A Southwestern Alaska Perspective

Dennis Griffin
Oregon State Historic Preservation Office,
Salem, OR, USA

Alaska is the home of many diverse Native peoples who inhabit a wide variety of environments. To survive and flourish in these environments, it was essential for people to be aware of the wide range of plant and animal species in their area on which their survival depended. Published texts on Alaskan Natives, particularly the Eskimo (Lee & DeVoreore, 1968), have stressed the dependence of Native people on hunting in order to survive. While this dependence is undoubtedly true, the awareness and intensity of use of vegetal resources has often been overlooked. While it is impossible to summarize, in a single entry, the use of indigenous plants among all Native peoples of Alaska, this entry focuses on one area of Alaska, that of the Southwest, in order to illustrate the range of knowledge and use of indigenous flora by the Yup'ik Eskimo. This use includes the harvest of plants for food, medicine, and utilitarian purposes. Limited ethnobotanical references for Native peoples in the remainder of the state are also included.

Alaska can be divided into two principal environmental regions based on general landform and vegetation: the interior and coastal regions.

Ethnobotany of Alaska: A Southwestern Alaska Perspective, Fig. 1 Distribution of Yup'ik speakers in Alaska

The interior region is bounded by mountain ranges to the north and south (Brooks and Alaska Ranges, respectively) with a gradual transition in elevation west to the Bering Sea. American Indian peoples largely inhabit the interior. While not being addressed in this entry, the ethnobiology of this region can be found in Carroll (1972), Fortune (1988), Garibaldi (1999), and Kari (1987). The coastal region extends along the border of the state to the north and west where it meets the Bering Sea and along the southern coastal area where it borders the Sea of Alaska. The northern and western coastal areas are generally icebound in winter and comprised of low-lying tundra vegetation. The southern coastal area is generally less affected by the ocean climate with its warmer sea temperatures with vegetation changing from a tundra regime on the Alaska Peninsula to a more forested environment to the east. The coastal region is largely occupied by Eskimoan people that are divided into two linguistic subgroups, the Yup'ik and Inuit-Inupiaq (Woodbury, 1984). (The Aleut

occupy the southern tip of the Alaskan Peninsula and the Aleutian Islands. Their use of indigenous flora is not discussed in this paper (see Bank, 1953).) Yup'ik was spoken aboriginally on the coasts of the Chukchi Peninsula in Siberia and Alaska from Norton Sound south to the Alaskan Peninsula and then east along the Pacific to Prince William Sound (Fig. 1). Inuit-Inupiaq was spoken north from Norton Sound and east across Arctic Alaska and Canada to the coasts of Labrador and Greenland (see Anderson, 1939; Nickerson, Rowe, & Richter, 1973; Jones, 1983 for ethnobotanical information for the Inuit-Inupiaq portion of Alaska). This entry focuses on the ethnobotany of the Yup'ik Eskimo in southwestern Alaska, an area dominated by the Yukon-Kuskokwim Delta which includes both Nunivak and Nelson Islands.

Few early ethnographic studies in Alaska have highlighted the Eskimo's range of knowledge and use of local flora. In fact the opposite was often the case, in that many observers expressed a belief that Eskimos had little knowledge of local

herbs and roots (Whittaker, 1937, p. 115). Young and Hall (1969, p. 43) found that the Western Eskimo were more aware of and made use of more plant species than is generally acknowledged. While the present study summarizes the known traditional use of indigenous plants in southwestern Alaska (central Alaskan Yup'ik), comparative data are also included for plant use among the peoples of St. Lawrence Island and Siberia (Siberian Yup'ik) and the Chugach of Prince William Sound (Pacific Yup'ik), when known. This information was primarily obtained from a 12-year (ca. 1995–2006) collaborative

anthropological project with the Nuniwarmiut of Nunivak Island (see Figs. 2 and 3) and a compilation of published and unpublished sources of ethnobotanical use.

Regional Setting

The Yukon-Kuskokwim Delta (Fig. 4), a geographic and cultural area historically occupied by central Alaskan Yup'ik-speaking Eskimos in southwestern Alaska, encompasses an area of almost 81 million kilometers (31,250 mile²) or

**Ethnobotany of Alaska:
A Southwestern Alaska
Perspective, Fig. 4** Map
of Yukon-Kuskokwim
Delta

E

8.1 million hectares (20 million acres). This delta region consists of a vast and largely roadless expanse of low-lying tundra that has attracted limited attention from ethnographers in the past. Native villages are located along the area's major waterways with development largely limited to commercial fishing. The degree of early contact between subcultural groups within the delta cannot accurately be determined due to conflicting early historical data and later movements of peoples throughout the region, but villages are

known to have been linked by extensive trade networks, intermarriage among village residents, and village alliances during times of warfare (VanStone, 1984, p. 224). Ponds, lakes, streams, and sloughs, which made travel throughout southwestern Alaska extremely difficult, cover half of the Yukon-Kuskokwim Delta. Not surprisingly, the immense wetlands provide suitable habitat for millions of waterfowl, small and large mammals, and abundant flora. The seasonal harvest of marine mammals (e.g., seals, sea lion,

walrus) and many species of fish (particularly salmon, halibut, whitefish, and blackfish) remains vital for local survival.

The Yukon-Kuskokwim Delta is subject to a subarctic maritime climate, influenced by the surrounding sea, which produces a relatively stable temperature. Summers are generally cool and windy, with some areas experiencing frequent fog; winters are cold with both wet and dry periods. The region's mean annual temperature is -2°C (30°F) with mean daily temperatures ranging from -25°C (9°F) in January and February to 10°C (50°F) in August (Selkregg, 1976; Swanson, Devony, Jenny, & Dale, 1986). Rain and snowfall are heavier on the mainland than neighboring islands (e.g., Nunivak), with islands experiencing more frequent overcast days with dense fogs. This difference between the mainland and island delta regions is due to the greater effect of the Bering Sea on the island environment. Precipitation is moderate with a mean annual rainfall of 40.6 cm (16 in.) and snowfall of 127 cm (50 in.). Vegetation throughout the region remains similar.

The Yup'ik Eskimo of southwestern Alaska traditionally practiced a hunting, fishing, and gathering subsistence economy that revolved around the harvest of the above-mentioned species, in addition to the numerous plant species that were critically important to survival. Hulten (1966, 1968) has studied the vascular flora of the Yukon-Kuskokwim Delta, Bos (1967) and Palmer and Rouse (1945) that of Nunivak Island, and Young (1968) on St. Lawrence Island. The region's vegetation is predominantly comprised of Arctic tundra containing a variety of lichens, grasses, sedges, flowers, and shrubs. It is similar to vegetation found throughout western and northwestern Alaska. The tallest tundra plants are shrubby willows that can reach up to 8 ft in height along some river courses. Major vegetation types include wet tundra, dry tundra, alpine tundra, and grass-browse (i.e., grass hummock and beach grass-forb). Wet tundra is most prevalent along the coast in poor drained areas, with the dominant cover species consisting of sedges (*Carex* spp.), cottongrass (*Eriophorum* spp.), willow (*Salix* spp.), crowberry (*Empetrum nigrum*),

and various species of mosses and lichens (e.g., *Sphagnum*, *Pohlia*, and *Cladonia*). Dry tundra is found on areas of sloping terrain having good drainage and is dominated by species similar to those found in wet tundra areas, in addition to bearberry (*Arctostaphylos alpina*), Labrador tea (*Ledum palustre decumbens*), woodrush (*Luzula nivalis*), bog blueberry (*Vaccinium uliginosum*), and dwarf birch (*Betula nana exilis*). Alpine tundra, found at higher elevations on hills and mountains, is similar to that in dry tundra areas and is dominated by crowberry, alpine bearberry, Labrador tea, white mountain avens (*Dryas octopetala*), and moss. Grass-browse is generally found interspersed with the dry tundra subtype and along edges of streams and rivers adapted to periodic flooding. This vegetation type is dominated by fescue (*Festuca* spp.), bluejoint (*Calamagrostis canadensis*), willow, lichens, sedge, wild celery, and seacoast angelica (*Angelica lucida*).

Use of Indigenous Flora

Indigenous plants were an integral part of the year-round diet of Eskimo people in addition to their incorporation in other facets of their lives. Contrary to the popular perception of Eskimo people surviving solely on fish and meat, they utilized a large number of local plants for food, medicinal, and utilitarian purposes. An earlier Alaskan study estimated that up to 15 % of the diet of Western Eskimo people (Kotzebue to Alaska Peninsula) is made up of vegetable resources (Young & Hall, 1969, p. 43). While plant resources remained sparse on some offshore islands such as St. Lawrence Island (Young & Hall), on Nunivak and Nelson Islands they provided a significant addition to the Native's year-round diet.

Knowledge of the Native use of indigenous flora in the delta remains limited. Previous ethnobotanical studies are limited to research on Nunivak Island (Fries, 1977; Griffin, 2001, 2004; Lantis, 1946, 1959; Nuniwarmiut Taqnelluit, n.d.); Nelson Island (Ager & Ager, 1980); the Kuskokwim villages of Napaskiak

(Oswalt, 1957), Eek, Kasigluk, and Nunapitchuk (Andrews, 1989; Lantis, 1958, 1959); and several lower Yukon Delta and coastal villages (e.g., Alakanuk, Sheldon's Point, Scammon Bay) by Fienup-Riordan (1986). St. Lawrence Island and the Chukchi coastal area of Siberia are similar in landform with southwestern Alaska in that lands are covered by low-lying Arctic tundra, although the number and variety of plant species differ between areas. Knowledge of the indigenous use of plants in these areas remains limited to few published and unpublished accounts (Ainana & Zagrebin, unpublished data; Young & Hall, 1969, respectively). Ethnobotanical knowledge among Pacific Yup'ik speakers is largely limited to studies among the Chugach (Birket-Smith, 1953; Fortuine, 1988; Wennekens, 1985) in Prince William Sound, Kodiak Island (Graham, 1985), and the Alaska Peninsula (Morseth, 2003). Since the flora of the first two of these areas is very different from that of the Yukon-Kuskokwim Delta (i.e., forest vs. tundra), only information on the use of similar plant species is addressed here. Several recent, regionally based publications have attempted to summarize our knowledge of the indigenous use of plants throughout Alaska (e.g., Biggs, 1999; Garibaldi, 1999; Schofield, 1989); however, the Yup'ik-speaking areas remain poorly documented.

Table 1 provides a list of the seasonal use of indigenous food plants by the Yup'ik Eskimo. This index provides data on the Yup'ik use of 43 indigenous plant species in southwest Alaska. In Table 1, species are arranged in alphabetical order by each species' botanical name. Details regarding season of harvest, plant part used, and if the species was stored for winter consumption/use are provided. In addition, the known range and extent of use of each species among Eskimo peoples is included.

While some researchers believed Eskimos had no knowledge of herbs or roots to combat or relieve sickness (Whittaker, 1937), this has been found to be untrue. Medicinal knowledge of indigenous plants varies from area to area with over 28 plant species used in the Yukon-Kuskokwim Delta. Table 2 provides a list of

medicinally used plants in the region, along with specific references to texts that provide greater detail on the collection, processing, and application of each species.

In addition to the use of plants for food and medicine, many plant species were used for a variety of utilitarian purposes. Table 3 provides details on 13 species used in southwestern Alaska. Data on plant name, season of harvest, and specific use is included.

Native Plant Taxonomy

An examination of general Yup'ik terms (Jacobson, 1984) provides comparative data useful in distinguishing some basic plant terminology distinctions. Yup'ik speakers (including Cup'ig speakers on Nunivak Island who speak the most divergent dialect within the Yup'ik branch) tend to divide plants into basic groups based on how plants were traditionally used, their similarity in appearance, or physical characteristics. For example, on Nunivak Island, the Cup'ig plant named *ciwassit* translates to "wild greens that can be cooked" and is used to denote several distinct species that are prepared in a similar manner (i.e., *Rumex arcticus* [sour dock], *Polygonum bistorta* [bistort], and *Polygonum viviparum* [alpine bistort]). (Cup'ig spellings of all plant species are taken from the Cup'ig Dictionary by Amos and Amos (2003) and have been placed in bold italics. A glossary of Yup'ik and Cup'ig plant names is included in the Appendix.) *Kumarutet* is used to denote all moss species (e.g., *Pohlia nutans*) based on the traditional use of moss as a wick in lamps (*kuman* = lamp, light). Examples of plants grouped by similarity in appearance, characteristics, or setting include (1) *elquat*, term used to designate several varieties of seaweed (e.g., *Palmaria palmata* [dulse], *Fucus* spp. [bladderwrack]); (2) *megtat neqiat*, meaning bumblebee food for several local plant species (e.g., *Pedicularis verticillata* [wooly lousewort], *Sedum rosea* [roseroot]); and (3) *agya an'a(i)*, used for all puffball species (*Lycoperdon* spp. and *Calvatia* spp.). In Yup'ik, *agya ana* translates to meteor and meteors,

which are traditionally said to turn into puffballs when they land (Jacobson, 1984, p. 48). Still other plant names highlight distinctions within a genus such as *qugyuguat*, which is used to refer to all *Salix* (willow) species except those exhibiting catkins, which are referred to as *qimugkararat*. Further analysis is needed in order to fully understand the Yup'ik's concept and categorization of local flora.

A similarity of plant use and some Native plant names between Yup'ik, Cup'ig, and Inupiaq speakers (i.e., Seward Peninsula) to the

north have been identified. Similarities between some Yup'ik, Cup'ig, and Inupiaq plant names (e.g., *kavlak-kavlag-kavlaq* [*Arctostaphylos alpina* (alpine bearberry)], *paunraq-paunrat-paungaq* [*Empetrum nigrum* (crowberry)], *pekneq-pekner-pikneq* [*Eriophorum angustifolium* (cottongrass)], *tukaayug-tuk'ayut-tukaayuk* [*Linguisticum scoticum* (lovage)]) and food preparations (e.g., *akutaq-akutar-akutuq* [Eskimo ice cream comprised of berries, seal oil, reindeer tallow (Crisco), snow, and sometimes salmon eggs]) highlight extended

contact between western Alaskan peoples over time. Further research is needed to evaluate the degree of sharing between these language branches with regard to the recognition and use of indigenous plants.

Plant Harvest, Preparation, and Storage

In the Yukon-Kuskokwim Delta, women and children traditionally gathered most indigenous plants, while the men were harvesting other available resources (e.g., caribou, waterfowl, seal) (Fienup-Riordan, 1983; Lantis, 1946). While fresh spring greens provided a welcome addition to the diet, which in winter was based largely on dried and stored foods, other greens were harvested throughout the year as they ripened and used with some of those stored for winter use. With the melting of the winter’s snow pack, local greens and berries not picked during the previous fall’s harvest begin to appear and were added to the local diet. Depending on the time the ice pack began to break up, Yup’ik families

began to move to their spring camps to harvest available resources. Along the coast, Yup’ik men would journey out along the ice to harvest arriving sea mammals (i.e., seals, walrus), while women would spend much of their time harvesting available plant resources (greens and seaweeds) and shellfish. Early harvestable spring food plants included marsh marigold (*Caltha palustris*), sour dock (*Rumex arcticus*), wild celery, wild lettuce (*Draba hyperborea*), wild parsnip (*Ligusticum hultenii*), wild rhubarb (*Polygonum viviparum*), mountain sorrel (*Oxyria digyna*), Pallas buttercup (*Ranunculus pallasii*), and Labrador tea.

After the completion of the spring hunting season, families would move to summer fish camps. Fish comprised the most prolific and essential subsistence resource for many Alaskan Natives living in the Delta, and its harvest would occupy the majority of the families’ efforts for several months. Traditional indigenous plants would continue to be harvested as they ripened and were eaten fresh or placed in underground caches for temporary storage.

Ethnobotany of Alaska: A Southwestern Alaska Perspective, Table 3 Utilitarian use of indigenous plants by Yup'ik-speaking Eskimo

Scientific name	Common name	Season	Plant part	Purpose	Location
<i>Aconitum delphinifolium</i>	Monkshood	Year-round	Root	Hunting poison	Chugach, Nunivak?
<i>Angelica lucida</i>	Wild celery	?	Root	Hunting talisman	Siberia
<i>Carex</i> spp.	Sedges	F	Grass	Boot lining, socks	Y-K Delta
<i>Cladonia rangiferina</i>	Lichens, reindeer moss	Year-round	Plant	Seal oil applicator	Y-K Delta
<i>Elymus mollis</i>	Wild rye grass	S, Su, F	Grass	Menstrual pad, basket roof thatching, mats	Y-K Delta Chugach
<i>Empetrum nigrum</i>	Crowberry	Su, F	Leaves	Storage pit liner	Y-K Delta
<i>Equisetum arvense</i>	Common horsetail	S, Su, F	Stems	Play matches for child	Y-K Delta
<i>Eriophorum angustifolium</i>	Tall cottongrass	?	Reeds	Basket, mat	K. Delta
<i>Petasites frigidus</i>	Coltsfoot	Su, F	Leaves	Berry basket	Nunivak
<i>Pohlia nutans/Webera nutans</i>	Moss	S, Su, F	Plant	Diaper, basket lining, fire starter, pottery pad	Y-K Delta Chugach
<i>Rumex arcticus</i>	Sour dock	Su, F	Plant	Navigation aid, cache pit lining, landmark	K. Delta
<i>Sphagnum</i> spp.	Sphagnum moss	Year-round	Moss	Menstrual pad, diaper	Nunivak
<i>Vaccinium vitis-idaea minus</i>	Lingonberry	Su, F	Fruit	Dye	Y-K Delta Chugach

E

By late summer/early fall, several berry species (e.g., cloudberry [*Rubus chamaemorus*], nagoonberry [*R. arcticus*], crowberry [*Empetrum nigrum*]) and local greens (e.g., sour dock [*Rumex arcticus*]) were ready to be harvested, and women and children would spend most days on the tundra gathering plant resources.

Most plants were available in a variety of locales, and their harvest did not dictate moving the family to specific camps. Plants that grew in abundance in specific terrain, such as several varieties of cliff greens, usually offered other

resources that could be harvested at the same time (e.g., fish, sandhill cranes). Greens such as *Rumex arcticus* could be found throughout the delta, and old camp sites are said to contain buried cache pits once used for plant storage.

As an example, when harvesting “wild spinach” or sour dock, Nunivak elders state that they would stay in an area until they had harvested enough for their family’s long-term needs (Amos, 1991; Kiokan, 1995). After picking, they would cook the spinach a little bit before placing it into a cache dug underground.

Cook em half way, just for the leaves to just shrivel up and not take much space, and they would dig ditches and line it with a certain type of twigs and grass and put em' in there until the weather gets colder, before the ground get hard, knowing that when it freezes, that *Ciwassit* (*Rumex arcticus*) would freeze in with the earth. So before that time they would go over there again, pull the *Ciwassit* out and this time leave em' on top of the ground. . . They would cover them with grass, probably willows too to keep them together and they would leave them until it freezes. (Amos, 1991, p. 16)

Before placing the spinach in the caches, the cooked leaves would be drained of juice and the pit lined with woven grass mats (e.g., *Elymus mollis*). "Some people rolled them up like a ball and put them away. Each roll was made enough for one meal. They rolled the spinach ball big enough for their dinner or a snack. That's how they took them out of the ground" (Amos, 1989, p. 25). Grass was placed on top before the cache was covered with rocks to insure it would not be disturbed until needed (Kiokan, 1995). Berries were stored in much the same way, except that these pits would be lined with rocks (Kiokan; Whitman, 1995), and raw spinach (e.g., *Rumex arcticus*) was used as an inner lining (Kiokan, 1995). The berries would have no juice when removed, since they would have dried out while being stored underground. In the fall, people would return to their seasonal caches and transport their stored berries and greens to their winter village. Curtis (1930, p. 36) describes berry caches as "a small box-like structure of flat stones lined with grass and covered with sod until air- and water-tight." Examples of such features were discovered during recent archaeological excavations on Nunivak Island (see Fig. 5).

Changes in Plant Use

While recent investigations on Nunivak Island (Griffin, 2001, 2004; Nuniwarmiut Taqnelluit, n.d.) have added extensive details to previous knowledge of traditional subsistence procurement and storage techniques, one must keep in mind that the memories of earlier subsistence use may be affected by historic changes to

Ethnobotany of Alaska: A Southwestern Alaska Perspective, Fig. 5 Rock-lined cache pits at Nash Harbor village, Nunivak Island, Alaska

Native culture. The most obvious change in Yup'ik indigenous plant use, between that found in early ethnographies and at present, is the current lack of knowledge of many previously harvested plants. With the abandonment of many small delta villages in favor of larger villages with established schools where Native children were sent to be educated, and a subsequent increased reliance on western foods, fewer families rely on traditional subsistence resources. Studies (e.g., Nowak, 1975) have documented a link between continued traditional subsistence activities and a family's economic position. With village centralization, the cost of purchasing and maintaining the equipment needed to continue traditional subsistence activities (e.g., boat, four-wheeler, gas) became dependent on having a steady source of income and time to pursue such activities. In time, information on earlier plant use is forgotten, and influences resulting from increased contact with non-Yup'ik mainland peoples can add to or supplant earlier local knowledge. For example, in 1927 Curtis (1930, p. 35) recorded the use of willow leaves (*Salix* spp.) on Nunivak Island as a food and medicinal item. In 1939, Lantis (1959, p. 60) found only one elder on Nunivak who still recalled the earlier use of willow. Today elders routinely deny such traditional use. However, recent influence of northern Eskimos on the island population has resulted in a renewed use of the plant, although contemporary Cup'it elders believe that its use is only of recent innovation. A similar pattern of

traditional versus recent use has been noted for stinkweed/wormwood (*Artemisia tilesii*).

It is easy to assume that observed Native lifeways in the early twentieth century reflect those practiced during the late prehistoric period or before. However, in spite of the evident continuity of tool use and general subsistence practices on Nunivak Island (Griffin, 2001, 2004) and the Yukon-Kuskokwim Delta (Shaw, 1983) throughout the past 500 years, traditional lifeways may have been different, possibly more complex, than those historically recorded. Following increased contact between mainland Native peoples (i.e., trade, intermarriage) and Euro-Americans during the nineteenth century, changes in the use of indigenous plants were probably an ongoing process, influenced by the degree and type of contact, as well as impacts from a serious loss in

Native population resulting from the introduction of western diseases.

Previous research in Native communities within the delta has focused on documenting changes to Native lifeways following the arrival of Euro-Americans to the region (e.g., Fienup-Riordan, 1983; Lantis, 1946). However, these studies have provided little detailed information on traditional use of indigenous plants. The collection of ethnobotanical information was rarely a focus of research efforts, and a systematic analysis of Native plant use throughout the region has yet to be undertaken. Given the incorporation of western foods in Native diets and a corresponding decline in the harvest of many indigenous plants, efforts to collaborate with Native communities need to be undertaken before information on traditional use of area vegetation has been forgotten.

<i>Valeriana</i> spp.	Valerian			ahseukpuk

^aName references same species but possibly different subspecies

The degree of contact between mainland and island Eskimo people, prior to the arrival of Russian and Euro-Americans in the late eighteenth and nineteenth centuries, is unknown but would have largely been limited to trade between neighboring groups during the summer months. Having to rely primarily on locally available resources for their subsistence, the Yup'ik incorporated many indigenous plants into their year-round diet. Contrary to earlier stereotypes of Arctic peoples' sole reliance on a meat-based diet for survival, local flora was routinely incorporated into the Yup'ik diet in addition to Native pharmacology and utilitarian tasks.

There are few Native elders with knowledge of traditional plant use in the Yukon-Kuskokwim Delta, and younger generations have not expressed a strong interest in preserving this data. Except for the continuing harvest of a few popular plant species (e.g., *Angelica lucida* [wild celery], *Rumex arcticus* [sour dock], *Caltha palustris* [marsh marigold], *Rubus chamaemorus* [cloudberry]), much traditional knowledge is not being passed on and will likely disappear with the passing of today's elders. It is important that additional research efforts to record traditional use of plants occur before knowledge of such use is forgotten.

Ethnobotany of Amazonia

Guillaume Odonne

CNRS, Cayenne, French Guiana, France

Amazonia is a place for myths and legends, and if it has been described for a long time as a “green hell,” it tends now to be perceived as a “green treasure,” with Native people keeping jealously the hidden secrets that may heal the whole planet. The truth is somewhere in the middle. Many people in Amazonia have a really good knowledge of their surrounding biodiversity and its uses, but this knowledge is unequally shared and rapidly eroding. Moreover, how Amazonian inhabitants use plants is a very dynamic field, due to the movements of people and the evolution of their culture. Summarizing Amazonian ethnobotany in a single encyclopedia entry is a challenging goal.

Amazonia is generally understood as the Amazon basin. Nevertheless, from ecological or anthropological points of view, this area is anything but coherent. In this entry, I will speak about the practices of the people from the tropical South American lowlands. This area encompasses the Amazon basin, i.e., the drainage area of the Amazon River and its tributaries, the Guiana shield, the North Brazilian shield, and the southern part of the Orinoco River basin. This region has an ecological homogeneity and a common cultural background. Mankind has been present in Amazonia for at least 10,000 years (Roosevelt et al., 1996). People came down from the north and appear to have spread over the area in a short period of time. According to the first Europeans testimony in the sixteenth century, human occupation in Amazonia was well organized and dense along the Amazon, with cities hosting thousands of inhabitants. But rapidly Amazonian societies faced an intense disorganization and split into smaller settlements. Now, Amazonia is a complex geopolitical region, encompassing more than 250 cultural groups. The majority of them are Native Americans, but many of them are mixed from African or

European descent. These different ethnohistories led to a rich corpus of plant uses that relies on a common Pan-Amazonian basis.

Historical Aspects of Amazonian Ethnobotany

Since the European discovery of South America, in addition to precious metals, plants became rapidly some of the most coveted goods. At the beginning it was simply wood for ships, then dye woods (*pau-brasil*, *Caesalpinia echinata* Lam.), and, finally, plants with medicinal properties (Manzali De Sá & Elisabetsky, 2012). The Jesuits early interest in Amazonian plant uses was followed, during two or three centuries, by a huge interest from the European countries for Amazonian economic botany. This led to many scientific (as well as political) expeditions, due to the dependence of European societies on natural fibers, spices, and remedies. The main part of the inventories was done by European naturalists such as the German C. F. P. von Martius or the French A. de Saint Hilaire, and their missions were scientific as much as diplomatic (Brandão et al., 2008; Brandão, Pignal, Romaniuc, Grael, & Fagg, 2012; Breitbach, Niehues, Lopes, Faria, & Brandão, 2013). The series of “legendary” botanists-explorers ends probably with the American R. E. Schultes, author of *The Healing Forest*, among other books, a milestone in Amazonian ethnobotany.

Between the late nineteenth and early twentieth centuries, there was an intensive exploitation of natural resources. The main natural product exported was rubber (*Hevea brasiliensis* (Willd. ex A. Juss.) Müll. Arg. and related spp., Euphorbiaceae). The close-to-slavery management system of the rubber harvest, the *aviamento*, led to the enrichment of a handful of *seringual* (*Hevea* grove) owners in the main harbors: Iquitos, Manaus, and Belem. Besides rubber, plants such as the *barbasco* (*Lonchocarpus utilis* A. C. Sm. and related spp., Fabaceae) were also exploited for export as agricultural insecticides. These cultivated or wild lianas, also called *timbo* or *cubé*, are traditionally used as a fishing poison.

People crush their roots and drop them into water to stun fishes so that they can collect them easily (Duke & Vasquez, 1994). These plants are rich in rotenoids, a class of isoflavonoid-derived compounds known for their ichthyotoxic properties. They were largely cultivated during the middle twentieth century and exported under the name of *cubé* resin (Fang & Casida, 1999; Schultes & Raffauf, 1990).

Different Faces of Amazonian Medical Ethnobotany

Two levels have to be distinguished when speaking about medical ethnobotany. Each group has its own specialties, and even every single village from the same cultural group has its own knowledge. On the other hand, there are common Pan-Amazonian popular medicines, which are shared from Iquitos to Belem. This common pharmacopoeia originates from a history of exchange between all these Amazonian cultures, as people move constantly from villages to the cities (San Lorenzo, Iquitos, Tabatinga, Manaus, Santarem, and Belem are some of these) to sell local products and return with goods and money. This has been one of the pillars of Amazonian economy (Emperaire, Aubertin, Bahri, & Bressolette, 1996). It consists in harvesting, in a relatively sustainable way, products or raw materials from the forest. Among them, we find *piassaba* fibers (*Leopoldinia piassaba* Wallace, Arecaceae), *babaçu* oil (*Attalea speciosa* Mart. ex Spreng., Arecaceae), Brazil nuts (*Bertholletia excelsa* Bonpl., Lecythidaceae), *açaí* (*Euterpe oleracea* Mart., Arecaceae), *copaiba* (*Copaifera* spp., Fabaceae), and many more. Those products are known by everybody in Amazonia and are found in every market in the region.

On the other hand, specific pharmacopoeias are found in different cultural groups, with some overlapping. It is now estimated that approximately 3,000 plant species are used medicinally in Brazil (Manzali De Sá & Elisabetsky, 2012). Nowadays, the plant uses of many groups in Amazonia are well described. Some of the most consistent works are those by Schultes and

Raffauf (1990), Balée (1999), or Grenand, Moretti, Jacquemin and Prévost (2004), and a good compilation has been established by Duke and Vasquez (1994).

Amazonian ethnomedical practices rely on a kind of dual system, which can be schematized as follows. Illnesses may be caused by spirits. Those spirits, often called “mothers,” are related to places, games, animals in general, meteorological events, or plants. They can harm people, and the main way to be healed is to consult a spiritual healer who will intercede between the malevolent entity and the patient. The therapies often rely on psychoactive plants, such as *tobacco* (*Nicotiana tabacum* L., Solanaceae), *ayahuasca* (a combination of *Banisteriopsis caapi* (Spruce ex Griseb.) C. V. Morton, Malpighiaceae, with *Psychotria viridis* Ruiz. and Pav., Rubiaceae), *toé* (*Brugmansia aurea* Lagerh., Solanaceae) or *chiric sanango* (*Brunfelsia grandiflora* D. Don ssp. *schultesii*, Solanaceae) (Schultes & Raffauf, 2004). But healers (*curanderos* in Spanish-speaking parts of Amazonia) may also be harmful, as they can send their own allied spirits to harm other people. This makes Amazonia look like a complex network of *curanderos*, spirits, and patients, involved in relationships of healing, killing, and revenge. Lay people are also aware of a certain number of magical plants, among which the *piri piri* are probably the most important. They (nearly) all belong to the genus *Cyperus* (Cyperaceae) and are cultivated around the houses and jealously cared for (Plowman, Leuchtmann, Blaney, & Clay, 1990), and their uses are often kept secret so they will not be stolen by neighbors.

However, a majority of daily ailments, considered “naturals,” or at least not from malignant origin, are healed at home or by people who have a particular knowledge of medicinal plants. These practices are still vivid, although primary health centers are now present nearly everywhere and accessing biomedicine is no longer a challenge. Knowledge of these plants is seen as a common phytotherapeutical background and is often shared at the community level. The diseases they heal are mostly perceived as not related to spirits. The complementarities between

these two medical levels, the *curanderos* and the *medicina casera* (home medicine), are the basis of Amazonian medical systems.

Now there is a clear tendency towards homogenization throughout the region, as a global Pan-Amazonian pharmacopoeia is replacing the particular knowledge of each specific group (Lenaerts, 2005). It is characterized by the predominance of cultivated plants around the houses, a small number of highly valued panaceas known with their Spanish (or Quechuas) or Brazilian names (e.g., *ajo sachá*: *Mansoa alliacea* (Lam.) A. H. Gentry, Bignoniaceae), and a high use of these “Pan-Amazonian” plants found in every herbal market (e.g., *sucuuba*, *Himatanthus sucuuba* (Spruce) Woodson and other spp., Apocynaceae, or *copaiba*, *Copaifera reticulata* Ducke L. and other spp., Fabaceae).

Some Important Medicinal Plants from the Amazonian Markets

Among those plants whose knowledge is widely shared throughout Amazonia, there are a handful of important ones, either for their historical, medicinal, or economical points of view, and they can still be observed in the markets. All are known since pre-Columbian times by Amazonian peoples, even if their uses have probably changed since those times. Some of them have been subject to exportation since the seventeenth century.

Andiroba (*Carapa guianensis* Aubl., Meliaceae)

Andiroba's oil is extracted mechanically from the seeds of *Carapa guianensis*, a tall tree from the Meliaceae family, and is sold in the main markets of eastern Amazonia. This fatty oil is principally used as a repellent against insect and tick bites and is the adjuvant of the *anato* red body dye (*Bixa orellana* L.) largely used by Amazonian Indians to paint their bodies. *Andiroba* oil is also claimed to be anti-inflammatory and contains molecules of the class of the limonoids (Silva, Oliveira & Figueiredo, 2009). It is used both on a small scale and industrially to produce soap.

Copaiba (*Copaifera reticulata* Ducke and Related Spp., Fabaceae)

Copaiba oil (or *copahu*), despite its name, is not a fatty oil but a sesquiterpene- and diterpene-rich oleoresin (Langenheim, 2003). It is extracted from several *Copaifera* species, trees from the Fabaceae family (Caesalpinioideae), after tapping (scarifying or piercing) the trunks. The most useful species seems to be *C. paupera* (Herzog) Dwyer, *C. multijuga* Hayne, or *C. officinalis* L. (Fabaceae) (Duke & Vasquez, 1994; Schultes & Raffauf, 1990). The composition and aspects of the oils vary depending on the species, but all are used as strong antiseptics, anti-inflammatories, and for wound healing (Veiga, Rosas, Carvalho, Henriques, & Pinto, 2007). Their commercial exploitation is very important in Brazil, and they have been exported to Europe and United States where they are still present in official pharmacopoeias.

Ipeca (*Carapichea ipecacuanha* (Brot.) L. Andersson, Rubiaceae)

Ipeca (or *ipecac*, *ipecacuanha*) is a small shrub not restricted to Amazonia, as it can be found in the humid forests of Central and South America. As many plants from the Rubiaceae family, it is rich in alkaloids, such as emetin. Its roots were used as an amoebicide but it is now better known as an emetic for people who ingested poisons. Ipeca roots syrup has been widely present in European, US and Canadian pharmacopoeias (Ferreira et al. 2012).

Ojé (*Ficus insipida* Willd.; *Ficus anthelmintica* Mart.; Moraceae)

El *ojé* (or *lombriguera* in Brazil) is one of the most valued anthelmintic [used to destroy parasitic worms] latexes of the Amazon, although it is more used in the western than in the eastern part (De Amorin, Borba, Carauta, Lopes & Kaplan, 1999; Hansson et al., 1986). It comes from tall trees from the Moraceae family. This latex, although controversial because of its high toxicity (Hansson, Zelada & Noriega, 2005), is still widely used by the native population. The latex is drunk pure or diluted with fruit juice or alcohol to get rid of intestinal worms. The properties are due

Ethnobotany of Amazonia, Fig. 1 *Sangre de grado* (*Croton lechleri* Müll. Arg.)

to an enzyme of the protease class called ficin. The use of ojé is often associated with food and salt prohibition (Duke & Vasquez, 1994).

Sangre de Grado (*Croton lechleri* Müll. Arg. and Related Spp., Euphorbiaceae)

The dragon's blood (*sangre de grado*) is a bright red latex (Fig. 1) extracted from several species of the *Croton* genus, medium-sized trees belonging to the Euphorbiaceae Family. The other numerous drugs with the same appellation, extracted from *Daemonorops* spp. (Arecaceae) or *Dracaena* spp. (Asparagaceae), are not American. The main species used is *Croton lechleri* Müll. Arg., but others, like *C. draconoides* Müll. Arg., *C. urucurana* Baill., or *C. palanostigma* Klotzsch, are also used the same way (Gupta, Bleakley & Gupta, 2008). The latex is used externally as a cicatrissant [to close a wound by scar formation] (Duke & Vasquez, 1994; Odonne et al., 2013), due to an alkaloid called taspine (Vaisberg et al., 2007).

Sucuúba (*Himatanthus sucuuba* (Spruce) Woodson and Related Spp., Apocynaceae)

Sucuúba (in Brazil), or *bellaco caspi* in the Spanish-speaking parts of Amazonia, is a small tree belonging to the Apocynaceae, exuding a white and abundant latex. Its external use against leishmaniasis or wounds seems to be widespread (Odonne et al., 2013; Schultes & Raffauf, 1990; Villegas et al., 1997) but it is sometimes sold on Brazilian markets against ulcers or digestive conditions (van den Berg, 1984). Its main compounds are iridoids and triterpenoids (De Miranda et al., 2000; de Silva, Amaral, da Silveira, Rezende & Pinto, 2007).

Conclusion

Amazonian ethnobotany is a multifaceted subject. Traditional uses of plants by the native inhabitants have changed a lot since the colonization of Amazonia by the Europeans. The place of the spiritual traditional healer, using few but powerful plants causing altered states of minds, is still paralleled by a general phytotherapy, individualized by each culture. Nowadays, it is also evident that a general Pan-Amazonian phytotherapy is emerging along the main routes of the Amazon, and it has not been established yet whether it is to the detriment of culture or not. Industrial plants also played a great part in the Amazonia's exploration and history. If rubber and *barbasco* are no longer of importance, the emergence of *açaí* berry-derived products exemplifies the high dependence on foreign fashions.

Ethnobotany of the Aztecs

Jan G. R. Elferink

Scope

The Aztecs represented the ruling empire in Mexico when the Spaniards arrived there in 1519. It was their culture that came in close – and for the Aztecs disastrous – contact with the Europeans. The Aztecs were a rather young culture. Starting as a small tribe in the thirteenth century, they developed into the ruling culture in Mexico. At the arrival of the Spaniards in 1519, the Aztecs ruled Central Mexico from their splendid capital Tenochtitlan, situated at the place where Mexico City is now located.

Ethnobotany in its broadest sense is the part of botany that deals with the use of plants in religion, medicine, all aspects of social life, and their interrelationships. The Aztecs used a very large number of plants. We know that because a lot were written down in the early years after the conquest. Because of space limitations, only a few aspects of Aztec ethnobotany will be dealt with in this article. The focus is on some plants that were especially important for the Aztecs. The relationship between medicinal plants and religion will also be discussed. A number of publications provide more detailed information about Aztec ethnobotany. These include the works of Ortiz de Montellano, Martínez, several articles in the work of Schultes and von Reis, and the comments by Emmart in the *Codex Badianus*. See also: <http://www.lib.utexas.edu/benson/bibnot/bn-92.html> and http://maya.ucr.edu/pril/reprints_agp/raiceetn.html. For the pre-Columbian use of plants in criminal practices see <http://www.drugtext.org/library/articles/elferink01.htm>.

Sources

A number of sources deal with the use of plants by the Aztecs. These works are more detailed

than for the Mayas or Incas, so we know a lot about their plant use. By far the most extensive source is the work of Hernández. He focused on medicinal plants; he described about 2,000 of them, but he also gave information about a large number of other plants. Hernández was the personal physician of Philip II of Spain. Philip sent him in 1570 to Mexico with a quite clear and specific order: to get as much information as possible from the indigenous herbalists, physicians, and other people involved in medicine. The work of Bernardino de Sahagún, a Franciscan monk, is by far the most valuable source of general information about the Aztecs. His work deals with all aspects of Aztec culture, but it also includes a lot of information about the use of plants. The importance of Sahagún lies not only in the abundance of information which he wrote down. It is especially his reliability, because of the procedure that he followed using Aztec informants. The *Codex Badianus* is an Aztec herbal, written by an Aztec physician in honor of and for Charles V of Spain. It contains colored figures of plants, and a description of the treatment of several groups of diseases. The importance of magic in Aztec medicine is quite clearly illustrated in this manuscript. For understanding the role of religion and magic in the use of medicinal plants two chroniclers are of special importance. These two, Hernando Ruiz de Alarcon and Jacinto de la Serna, wrote their works in the seventeenth century. This might seem late, but the mere fact that they tried to eradicate the ancient customs and beliefs demonstrates that they dealt with the beliefs and attitudes of the ancient Mexicans. In both works ample attention has been paid to the use of *ololiuhqui*, *peyotl*, *picietl* and other plants in medicine and religion. In addition a number of other chroniclers mention the use of plants, but mostly their contribution is modest as compared with those mentioned before (Fig. 1).

The Aztec Interest in Plants

Botanical Gardens

The appreciation of the leading Aztecs for botany, and especially for medical botany, is

Ethnobotany of the Aztecs, Fig. 1

In the Mexican codices plants (especially flowers) are often depicted, such as here in the Codex Nuttall. They are probably connected with medicine, but their exact meaning is often unclear

E

demonstrated by the presence of botanical gardens in ancient Mexico. Their wealth in species and choice was so large that the Spanish conquerors were deeply impressed. One of the most important gardens was near the palace of the ruler Montezuma. He did not want any food plant or fruit tree in his garden. Those, he believed, were for slaves and merchants. The garden contained medicinal plants, beautiful flowers, and odorous trees and herbs. Montezuma ordered his physicians to use the medicinal plants for the nobles at court (Cervantes de Salazar, 1971, p. 320). According to Solís the botanical gardens contained herbs for all types of diseases and ailments, and although the Aztec physicians had little knowledge of the cause of diseases, they knew quite well with which plants certain diseases had to be treated. The medicinal plants from these gardens were distributed freely to all those who suffered from diseases (de Solís, 1996, p. 172).

The king of the city-state Texcoco (which had a treaty with the Aztec capital Tenochtitlan) was Nezahualcoyotl; he lived in the fifteenth century. He is described as a constructor, a poet, a wise and clever statesman, and a righteous ruler who codified a number of laws (Clavijero, 1970, p. 115). He was also a special expert on medicinal plants. Those plants which he did not have in his vicinity – Texcoco is situated near present-day Mexico City at an altitude of about 2,000 m – were painted. Hernández used these

paintings when he prepared his treatise on the materia medica of Mexico; in the original version he meticulously copied figures of plants.

Clavijero (1970, pp. 231, 232) states that there were many botanical gardens in ancient Mexico. He mentions as the most important those of the capital Tenochtitlan, and that of Texcoco, and of the lords of Iztapalapa and of Huaxtepec. Cortés and Bernal Díaz expressed their admiration for the garden of Iztapalapa, and Hernández described a number of the plants from this garden. More important and also much larger than the garden of Iztapalapa was the botanical garden of Huaxtepec. The garden not only contained local plants but also many which were imported from regions far away. After the conquest the Spaniards conserved the garden for many years, and used the medicinal plants in the hospital which they had established in the region (Clavijero, p. 232). Clavijero stresses that many of the plants in this garden were taken from remote areas. The transportation of several types of trees from remote areas to the core of the Aztec empire was only one of the many classes of products which were transported. The conquered tribes had to pay a lot of tribute consisting of a large variety of goods, to the Aztecs. In addition the Aztec merchants, who traveled a lot abroad, transported valuable items (which could be plants) from the region where they practiced commerce, to the capital.

Medicinal Plants

Knowledge of medicinal plants was essential for the Aztecs because their treatment of diseases relied heavily on their use. The principal quality or application of the plant determined their nomenclature. That could be a color, the place where it was found, the beauty of the flower, but also its preferential application against a certain disease. The Aztecs often gave a plant the suffix *patli* when it was used as a medicine; *patli* means “medicine,” but gives by itself no further specification. The reference to a disease or target was often given in the remaining part of the name. In this nomenclature the plant *axixpatli* was a medicine which caused urination (a diuretic). In the same way the plant *atonahuizpatli* was a remedy against fever. In such a name the ability of the plant to act as a medicine against fever is stressed, but it does not necessarily mean that the plant had no other properties. Sometimes a large number of different plants had the same name. The disease *nanahuatl*, probably syphilis or a related disease, was very important in ancient Mexico (Fig. 2). Hernández gives not fewer than eight different plants which were called *nanahuapatli*. The Aztecs also had a medicine called *nanahuaquahuatl* or “tree against *nanahuatl*,” and *nanahuaxochitl* or “flower against *nanahuatl*.”

The Aztecs had a clear idea about the origin of their knowledge of medicinal plants. They were convinced that they had inherited this knowledge from the Toltecs, a tribe that resided in the valley of Mexico before the Aztecs arrived, and to whom the Aztecs were related. About the Toltecs Sahagún writes:

...the Toltecs had much experience and knowledge, they knew the properties and virtues of herbs, they knew which were harmful and poisonous... and through the large experience they had [of these plants] they passed on [the knowledge of] those which are now used for curing, because they were the first physicians, and especially the first of this kind who were called Oxomoco, Cipactonal, Tlaltetecuín, and Xochicauaca who were so competent in knowing medicinal herbs that they were the first inventors of medicine, and the first physician-herbalists. ... (de Sahagún, 1969, p. 10-XXIX).

Ethnobotany of the Aztecs, Fig. 2 It is striking that the *Guayacum officinale* or guayacan was not described as one of the *nanahuapatli* (medicines against syphilis). The guayacan became a major medicine for the Europeans who suffered from syphilis. This picture is from Köhlers *Medizinal-Pflanzen*

The description underlines the importance of medicinal plant knowledge, in a way that demonstrates that medicine and botany could not be separated.

Plants in Religion and Medicine: Divine Plants

The Aztecs venerated a large number of gods, and a number of them had a close relation with plants. The goddess Toci was venerated by all those who had a profession related to medicine (de Sahagún, 1969, pp. 1-VIII and IX). She was the goddess of medicines and medicinal plants. Like other social entities in the Aztec society the pharmacists venerated their own deity. This was primarily the goddess Tzapotlatena. The fact that she had invented the *uxitl*, a highly appreciated medicinal resin derived from pines, was the reason that the

Ethnobotany of the Aztecs, Fig. 3 One of the maize goddesses, named Xilonen, depicted in the Codex Nuttall

pharmacists venerated her. For the invention of the resin she was immortalized and incorporated in the Aztec pantheon of gods and goddesses. Because of the importance of maize as a food plant, some gods were especially associated with maize: Cinteotl, and the related deities Xilonen (Fig. 3). Aztec tobacco or *picietl* was also closely linked to religion. It was believed that tobacco was the body of a goddess called Cihuacoatl (Mendieta, 1973, pp. 66, 67).

Some time after the conquest a number of priests tried to eradicate the ancient beliefs of the Aztecs (de la Serna, 1953; Ruiz de Alarcon, 1953). These priests reported about their activities, and from these reports we can learn how high the Aztecs appreciated a number of plants. In fact, the priests described these plants as divine plants, because they were venerated as (minor) gods. They were invoked by means of incantations or prayers, for help with diseases. Among these were *ololiuhqui* (*Rivea corymbosa*), *peyotl* (*Lophophora williamsii*), *picietl* (*Nicotiana* sp.), *huauhtli* (amaranth, *Amaranthus leucocarpus*), and *yauhtli* (*Tageta lucida*). They had in some way or other a connection with the supernatural. Some of them were hallucinogens, and could be

used to get into a trance to make contact with supernatural powers (Fig. 4). These hallucinogens were used not only for divination purposes, but also in medicine. The religious relevance of the plants varied; the *ololiuhqui* was especially venerated as a kind of god. On the other hand, the *picietl* (tobacco) was used most frequently against a variety of diseases. The *peyotl* was mostly considered in conjunction with *ololiuhqui*, while the *yauhtli* could sometimes substitute for *picietl*. *Yauhtli* (more correctly spelled: *iyauhtli*) was considered an important medicinal plant (Elferink, 1988) (Fig. 5). Hernández mentions more than 20 applications in Aztec medicine. A priest who asked the plant for a cure especially invoked *picietl*. At the same time it was applied to the patient. Occasionally other medicinal plants were invoked for special complaints. For example, the *poztecpatli* was a medicine against bone fractures. It was invoked in an incantation while the priest-physician applied the plant in the form of a plaster (Ruiz de Alarcon, p. 189).

A plant that was not hallucinogenic but nevertheless highly venerated by the Aztecs was *huauhtli*. The connection of *huauhtli* with religion was complex. It derived its importance not from incantations but from a special application in Aztec religion. From *huauhtli* a dough was made that was called *tzoalli*. From this *tzoalli* statues of gods were made. The statues were venerated and subsequently consumed in religious ceremonies as a kind of communion. *Huauhtli* was also an important food plant, and used against diseases such as eye complaints, swellings and pain in the chest.

Some hallucinogenic plants, namely *ololiuhqui* and *picietl*, had still another connection with medicine. They were principal ingredients of *teotlaqualli*. This was an unction that was offered to the gods, for whom it served as food. The Aztec priests smeared themselves with this unction, to dispel fear and to reach the appropriate state of mind to serve the Aztec gods. A few cases are reported in which the Aztec emperor or soldiers were smeared with *teotlaqualli*. It is suggested that the black color of some Aztec deities, as depicted in the codices, was due to an ointment with *teotlaqualli*. In addition to its use for psychoactive

Ethnobotany of the

Aztecs, Fig. 4 Besides the hallucinogens mentioned in the text the Aztecs used *teonanacatl*, the divine mushroom. In the lower part of the picture (Codex Nuttall) the mushroom is depicted, as well as a man who eats it and an unknown deity

Ethnobotany of the

Aztecs, Fig. 5 The Aztecs sacrificed many humans, as depicted here in the Codex Nuttall. On a few occasions they were stunned before they were sacrificed. According to Sahagún the *yauhtli* was used for this purpose

purposes, *teotlaqualli* was applied in medicine under the name *teopatli* (Elferink, 1999).

Some Plants with Special Interest for the Aztecs

Maize

The name maize comes from the language spoken in the Caribbean; the Aztec name was *tlaolli* (*Zea mays*). It was by far the most important food plant of the Aztecs. Its importance can be derived from the large number of Aztec gods that were associated with maize. Its use in medicine was

rather limited, although a number of chroniclers had a different opinion. They were convinced that the consumption of maize products was the cause of the low incidence of kidney and bladder complaints among the Aztecs. From maize a porridge called *atolli* was prepared. It was usually prepared together with other plants, and so a large number of different types of *atolli* were known. The *chillatolli*, for example, was *atolli* mixed with chili pepper. This *atolli* was an aphrodisiac, probably due to the pepper. Hernández describes nearly 20 different types of *atolli*, some of which were applied in medicine. It is hard to say

whether their supposed medicinal action was due to maize or to the other added products.

Picietl

There are few plants which played such a decisive role in Aztec medicine and religion as the *picietl* (*Nicotiana* sp.). *Nicotiana rustica* is often given as identification of *picietl* or Aztec tobacco, but the properties of *N. rustica* do not correspond with those of *picietl*. This refers especially to the mind-altering properties of *picietl*, and these properties especially determined its role in religion, magic, and curing with medical incantations as mentioned before. Many chroniclers have noted these psychoactive properties, so that there is little doubt about this property in ancient times. It is therefore not surprising that diviners used *picietl* to get intoxicated, so that they could make divinations. In addition to magic-religious applications in medicine, *picietl* was just applied as a medicinal plant. Hernández mentions its use against more than 20 different ailments, particularly ailments associated with pain. An interesting application was the use of tobacco as an antidote against the bite of various poisonous animals and the cleansing of wounds with tobacco juice. A particular application of tobacco was the stunning of dangerous snakes with tobacco powder, so that they could be caught for religious purposes (Elferink, 1983).

The Aztecs considered tobacco a sacred plant, and it was highly appreciated because of its use in medicine and its psychoactive properties. In this context it is relevant to realize that the Aztecs did not use the tobacco for recreational purposes as we use tobacco today. The Aztecs did not experience the negative effects of smoking, although they knew too that excessive use was dangerous.

Metl

The name *metl* or *maguey* was used for several Agave species. The *metl* was in more than one respect an important plant. It provided fiber that could be used for preparing clothes, sandals, and other materials. It was used to prepare a good quality of paper. The thorns were used as needles. A specific application of these thorns was the

pricking in the ears or genitals to obtain blood for an offering to the gods. *Metl* was the basis for the preparation of *octli*, today better known as the *pulque*, an alcoholic drink made by fermenting a honey-like secretion of the plant. Although the use of alcoholic beverages was forbidden under normal conditions, *octli* was so important in Aztec society that several Aztecs gods were associated with it. It was frequently used as an offering. Consumption of *octli* occurred mainly during festivities of some *octli*-gods. Both *metl* and *octli* were applied in medicine, the *octli* mainly as vehicle for the intake of other medicines. Pregnant women were allowed to consume *octli* outside religious festivals, because of the supposed strengthening action of the beverage (Fig. 6).

Ulli

Ulli or *hule* was the resin of the *olcahuitl* (or *holquahuitl*) tree (*Castilla elastica*), one of the rubber-producing trees of the Aztecs. It had a number of applications. The *hule* was the product from which balls were made for the ritual ball game. It was further used in a number of religious customs. One of them was related to medicine. If someone recovered from a disease he wanted to honor the god who was associated with the disease. For that purpose he went to a soothsayer-priest to select a suitable day. On that day the former patient burnt in his home pieces of paper on which the soothsayer had painted with *ulli* the picture of the god who had to be venerated (de Sahagún, 1969). The use of *ulli* as an offering to the gods is confirmed by other chroniclers (Durán, 1967: Calendario, V). The *ulli* was sold in the markets by special vendors, who sold nothing except *ulli* (de Sahagún, pp. 10-XXIV). One of the most important medical applications of the *ulli* was to treat dysentery and diarrhea (Hernández, 1959; *Relaciones Geográficas Tlaxcala*, 1984, p. 271; *Relaciones Geográficas México*, 1985, p. 318). For that purpose the *ulli* was often mixed with cacao. It was further used against a number of other ailments such as abscesses, eye diseases, inflammations, intestinal problems, urinary complaints, colic, pain, headache, and eye diseases (de Sahagún, p. 11-VI; Hernández). Hernández describes a peculiar

Ethnobotany of the

Aztecs, Fig. 6 From maize a beverage was prepared that was called *octli* (later it got the name *pulque*). Its consumption was forbidden under normal conditions but during some religious feasts it was taken in large quantities. Here the preparation and consumption of *octli*, as depicted in the Codex Nuttall

application of the ulli, which he apparently had learnt from indigenous physicians. Mixed with axin it was taken to improve the agility and speed of the joints. The informants told him that the bones were loosened in a sense that turns and movements were facilitated so that acrobatic abilities were obtained (Hernández).

Coanenepilli

Another plant, which is often mentioned by the chroniclers because of its frequent use by the indigenous population, is the *coanenepilli*. The name “serpent tongue” refers to the form of the leaves which are bi-lobed (Emmart, in *Codex Badianus*, 1940: plate 59). As might be expected, the name was used for completely different plants, namely *Dorstenia contrayerba*, and a *Passiflora* sp. For medicinal purposes the first one was by far the most important. In the *Codex Badianus* *coanenepilli* was prescribed against obstruction of the urinary tract. An important application of *coanenepilli* was its application as an antidote. For that reason it was called *contrayerba* by the Spaniards. If a snake or a scorpion bit someone, the Indians anointed the bite with the *coanenepilli*, while the juice of the plant was drunk (Relaciones Geográficas México, 1986, p. 150; Relaciones Geográficas Michoacan, 1987, p. 43). Another important application of *coanenepilli* was against fever

(Relaciones Geográficas México, 1985, pp. 280, 306, 312). The Aztec informants of Sahagún stress the ability of the *coanenepilli* to purge: bad humors were expelled by mouth and via stool de Sahagún, 1969, pp. 10-XXVIII).

Shortly after the conquest it was also applied against typhus (de la Serna, 1953, p. 283; Mendieta, 1973, p. 98; Relaciones Geográficas Tlaxcala, 1985, p. 205). The Aztecs desperately tried a number of medicines against the new diseases which were imported by the Spaniards. These diseases decimated the number of Indians, and caused depopulation of large parts of the country (see Chap. XIII). Among the few medicines used by the Indians against these new diseases, the *Relaciones Geográficas* mentions the *coanenepilli*. The frequent application of this plant could suggest that the Indians had some benefit from it. On the other hand, the number of casualties could hardly have been higher than it was, so the new drug had only a limited curative value (Relaciones Geográficas Tlaxcala, pp. 51, 54, 59). The reason for the use of this plant against epidemics was probably that the *coanenepilli* was regarded as a good remedy against feverish conditions. Because the postconquest epidemics were accompanied by fever, the choice for the *coanenepilli* was evident (Relaciones Geográficas Tlaxcala, pp. 84, 205).

Coanenepilli was popular in the combined treatment of diseases with medicinal plants and magic-religious incantations. If someone experienced chest pain because of an accident, the powdered root of coanenepilli was applied, and the patient had to drink a potion of the plant thickened with ground maize. At the same time an incantation was spoken where the coanenepilli was invoked in the name of the god Pahtecatli (Andrews, 1984, pp. 177–178). Combined with magic incantations the coanenepilli was further applied against fever and against cutaneous eruptions (Andrews, 1984, pp. 195–199; de la Serna, 1953, pp. 292, 293, 283, 289).

Iztauhyatl

The *iztauhyatl*, in Mexican folk medicine called *estafiate*, is botanically known as *Artemisia mexicana*. According to the Florentine Codex the plant was a remedy against many diseases (Florentine Codex, 1950–1969, pp. 11–VII). Relapsing fever, cough and anxiety are mentioned. The plant was useful for treating anxiety (de Sahagún, 1969, pp. 11–VII). It was also a part of complex medicines. In the Codex Badianus the *iztauhyatl* was part of a remedy against some diseases which we do not always know exactly what was meant: weakness of the hands, ailment of the fundament, injury of the feet, lassitude, excessive heat, lightning stroke, and phthiriasis of the head (Codex Badianus, 1940: plates 43, 61, 65, 66, 79, 91, 102). Hernández indicates that the name *iztauhyatl* was used for more than one plant. In most cases, however, the plant described as *iztauhyatl* was *Artemisia mexicana*.

Magic power was ascribed to the *iztauhyatl*, and it was considered a sacred herb (Aguirre Beltrán, 1987, pp. 124–126). According to Aguirre Beltrán the name of the plant is derived from *iztahua* (deity of the salt), and *atl* (water). The indigenous physicians called *techichinani*, who cured by sucking the illness from the body, chewed the *iztauhyatl* before they started the sucking of the disease. As a sacred plant the *iztauhyatl* was invoked in cases of troubles in love affairs. The magic power of the *iztauhyatl* was called for assistance when a pregnant woman

or her husband wanted to trespass some rules, such as leaving the house during the night. The result was quite nasty for the child to be born who would cry a lot or become ill. To prevent these dangers the woman had to wear a bag with some copal or *iztauhyatl*, and the man had to wear a bag with *picietl*, when they went out during the night (de la Serna, 1953, p. XIII; de Sahagún, 1969, pp. 5–XIX).

Against one of the most severe epidemics of the postconquest time, mostly referred to as *cocoliztli*, no medicines were available. Among the few which were tried with unknown success were the *iztauhyatl*. Some of the authors of the *Relaciones Geográficas* mention the plant as a remedy; it was put in water, and the water was used to wash the patient (Relaciones Geográficas Mexico, 1986, p. 135).

Ethnobotany of the Incas

Jan G. R. Elferink

The conquest of America resulted in a considerable enrichment of the number of plants that could be used by Europeans in medicine and nutrition. Important examples are the potato, maize, beans, cacao, chili pepper, quinine, and so on. All these plants were widely used by the pre-Columbian peoples, among which were the Incas. The Incas were only one of the many highly developed civilizations that developed in the Andes and the Peruvian shore of the Pacific Ocean. Like the Aztecs in Mexico, the Incas were a young culture, starting their development in the thirteenth century. When the Spanish conqueror Pizarro arrived in Peru in 1531, the empire of the Incas was enormous, stretching from what is now Colombia in the North, to the middle of Chile in the South.

Information about the use of plants in all aspects of daily life by the Incas (i.e., Inca ethnobotany) comes mainly from the Spanish chroniclers who accompanied or followed the Spanish

conquerors. Unfortunately their information is far more limited than of the chroniclers of the Aztec region. As a consequence we know less about Inca ethnobotany than about Aztec ethnobotany. The chronicler Cobo gave the most extensive description of Inca plants. Some indigenous chroniclers, such as Poma de Ayala, gave some original applications of plants by the Incas. A very late work by Losa contains material that was mostly derived from ancient sources (including Cobo), and thus provides information about the use of plants that is probably of pre-Columbian origin. Besides the information written down by the chroniclers, an increasing quantity of information comes from archeological findings.

Although the amount of information about the use of plants by the Incas is limited, the amount is far too large to cover in a short paper. Therefore only a restricted number of items of Inca ethnobotany will be dealt with. These items come from the use of plants in medicine, and in connection with their role in magic and religion. There is excellent additional information about Inca ethnobotany. These include the works of Yacovleff and Herrera, Towles, Alarco de Zadra, Bastien, Brack Egg, Valdizan, and Maldonado. Unfortunately some of these works are not easily accessible. A very good website about the potential economic applications of Inca food plants is <http://www.nap.edu/books/030904264X/html/>.

Medicinal Plants

The Inca Herbalist-Physician: Hampicamayok

In his description of the Inca physician, Cobo, (1964, p. 256) underlines the importance of the knowledge of medicinal plants for this profession.

... Their physicians were in general old people and highly experienced... They had little knowledge about the nature of the diseases and about their specific names... [They knew] many herbs to cure them. They had more knowledge about wounds and sores... and the particular herbs to cure them. They never used complex drugs, they cured with simple herbs, and between them there were many great herbalists... from whom we learned the virtues of many plants which we now

use in our cures. With these simple drugs they also used to make fomentations and perfumes, which they applied in fever and other ailments. . .

Other chroniclers such as Garcilaso confirm the importance of knowing plants among the Inca physicians. Though Garcilaso is sometimes contradictory in his descriptions of the medical abilities of the Incas he praises the herbalists. There were “great herbalists who were very famous in the days of the Incas. These herbalists learned the virtues of many herbs and taught them by tradition to their sons; they were regarded as physicians. . .” (Garcilaso de la Vega, 1966, p. 121).

The most common name for this type of physician was the *hampicamayoc*, literally “official in charge of medicines” (González Holguín, 1952; Morua, 1946, p. 113; Poma de Ayala, 1980). Calancha states that the (h)anpicamayos, who were called *oquetlupuc* in some coastal regions, were physicians with good reputations (Calancha, 1974, p. 1248).

Besides Cobo some other chroniclers made statements which give an idea of the knowledge about medicines of the indigenous herbalists. Without referring directly to the herbalist, Blas Valera stresses the large number of medicinal plants of the Incas. He says that if they were all known there would be no need to bring herbs from Spain or elsewhere, but that the Spanish doctors set so little store by them that even those which were known to be used by the Indians have in the main been forgotten (Valera, 1992, p. 132). It is not quite clear if the Kallawayas, the traveling herbalists of the Andean regions in Bolivia and Peru, knew the *hampicamayok*. About these Kallawayas (or Callawayas or Callahuayas) a large amount of information is available concerning their role in folk medicine of the last few centuries (Bastien, 1987).

Plants Used in Medicine

In contemporary Peruvian folk medicine a very large number of medicinal plants are used, but the chroniclers described only a relatively small number of them, only a few hundred. That does not mean that the Incas did not use them. It is more an indication that the chroniclers for the Inca region were far less competent than those

Ethnobotany of the Incas, Fig. 1 Maize or *sara* was an important food plant. According to the chroniclers, the consumption of maize products was the reason for a low incidence of gout among the Incas. This and the other botanical pictures are from Köhlers *Medizinal-Pflanzen*

of the Aztecs. Cobo has especially described many Inca plants. Among these were a few that were more important in Inca medicine than others. Maize or *sara* (*Zea mays*) was not only an important diet staple but was also an important medicine, as was the slightly alcoholic beverage called *chicha* that was prepared from maize (Fig. 1). According to several chroniclers the consumption of maize and *chicha* was the reason that they saw very few kidney and bladder complaints among the Incas (Fig. 2).

In the work of most chroniclers only a few plants are mentioned. It seems likely that those few plants mentioned repeatedly by different authors were of special importance and widely used. If this reasoning is correct then *molle* (*Schinus molle*) was one of the most used medicinal plants (<http://www.herrerros.com.ar/>

melanco/elferink.htm). Contreras y Valverde (1965, pp. 11, 12) states that the Indians considered the *molle* as a universal medicine against all their ailments. The differential use of *molle* is a good example to show that Inca physicians were quite aware that the eventual medicinal effect was dependent on preparation and means of application. The tree exudates a resin that was taken as a purgative and against melancholy; the resin in wine was against dropsy (Lizarraga, 1968, p. 81; *Relaciones Geograficas*, 1965: I-349; Vazquez de Espinosa, 1969, p. 432). To cure leishmaniasis the resin and the bark of the tree were boiled in water until the water remained colored, and from this fluid the Indians took a portion on an empty stomach, and a second portion in the afternoon (Cobo, 1964, p. 6-LXXVIII). The dried and pulverized resin was applied against ulcers. Lizarraga describes the resin as an excellent remedy for diseases of the respiratory system; he had tried the resin on himself (Lizarraga, 1968, p. 81). The leaves, cooked and applied in a bath, were used for gout, and the crushed leaves were applied on wounds (Cobo, 1964, p. 6-LXXVIII). The liquid made by boiling the leaves in water was a good remedy for eczema (Garcilaso de la Vega, 1966, p. 504). From the leaves a kind of oil was prepared that was useful for pain in the joints and for ailments of the stomach (*Relaciones Geograficas*, 1965: I-349). A decoction of the leaves was applied as a bath for the treatment of the swollen legs of dropsy patients, and for gout. A plaster of the fruits was supposed to be effective for stomach complaints (Cobo, 1964, p. 6-LXXVIII). The fruits of the *molle* were crushed and the juice gave a beverage that was taken for kidney and bladder complaints (Garcilaso de la Vega, p. 504). The fruit was also used to prepare a kind of *chicha*, which was more intoxicating than the *chicha* made from maize, and which was highly esteemed by the Indians (Cobo, 1964, p. 6-LXXVIII). Besides medicinal properties the *molle* possessed some other qualities. Its wood was preferred as the basis for charcoal. This was the reason that it lost its importance in colonial times. Before the conquest the tree was very common, but a few years after the conquest

Ethnobotany of the

Incas, Fig. 2 Ploughing by special implements as preparation for sowing maize was ceremonially initiated by the Inca ruler and his family, recognizable by the large earrings

it had decreased dramatically (Garcilaso de la Vega, 1966, p. 504) because of the need of charcoal for brasiers.

Another plant with widespread application was the *quinua* (*Chenopodium quinoa*). The plant was an important food-plant; it was especially attractive because it grew at high altitude. It was also used in medicine for a number of ailments such as stomach complaints, inflammations, spasms, swellings, fever, liver complaints and so on (Calancha, 1974, p. 138; de Losa Avila y Palomares, 1983, pp. 71, 72; Garcilaso de la Vega, 1966, p. 500). Another attractive feature was the possibility of preparing a good quality of inebriating chicha.

The *chamico* (*Datura stramonium*) was a strongly hallucinogenic plant (Fig. 3). In low doses the plant was used against fever, insomnia, inflammations, and to abate pain. According to Cobo the *chamico* was taken to get inebriated.

Higher doses were used in criminal practices, a custom that has persisted till modern times. According to Cobo the chamico was secretly administered to victims who became intoxicated, and thus could be robbed easily. The chroniclers do not report about the use of chamico in religion, in contrast with other psychoactive plants.

Some plants, such as *coca*, *sayri* (tobacco) and potatoes were especially important in social life as food plants or in religion as offerings (<http://www-personal.umich.edu/~jlvoris/thesis.html>). However, all of them were also used as medicine. Chewing of coca leaves was practiced to ease hunger, thirst and tiredness, and this habit became especially important after the conquest (Fig. 4). Coca leaves were applied externally to strengthen broken bones and to cure wounds and ulcers. The decoction was taken against diarrhea and to combat stomach complaints. The dried pulverized leaves were used for asthma. Coca was added to

Ethnobotany of the Incas, Fig. 3 *Datura stramonium* or *chamico* was used in medicine and in malevolent practices

tobacco and chewed maize in an ointment to treat the bites of poisonous animals (de Atienza, 1931, p. 75). Two types of tobacco were distinguished: a cultivated and a wild form. It seems likely that these two forms correspond with *Nicotiana tabacum* and *Nicotiana rustica*, respectively (Wilbert, 1987; <http://www.hoboes.com/html/Politics/Prohibition/Notes/Shamanism.html>). Both were used in medicine, but mostly it is not indicated which form was used. The root of the wild form was called *coro*, and was especially suited for a number of diseases, including syphilis. Tobacco was usually smoked, but the Indians used the tobacco also as snuff (Cobo, 1964, p. 4-LVI). Tobacco was used to treat headache and migraine, and to improve sight. Poma de Ayala states that tobacco, in the form of snuff, was used against fever and cold (Poma de Ayala, 1980, p. 769). One of the main applications of tobacco was to treat bites of poisonous animals (Apuntes, 1987, p. 14; Maroni, 1988, p. 157). The medical applications of potatoes were limited. Cooked

Ethnobotany of the Incas, Fig. 4 The coca plant played a role in Inca religion and medicine. Its use in pre-Hispanic times, however, was strongly regulated by the Inca ruler

potatoes were applied against gout. Potatoes were freeze-dried for conservation, and the resulting product was called *chuñu*. The *chuñu* was considered an excellent remedy against ulcers, spasms, pain of syphilis, and verruga (Cobo, 1964, p. 4-XIII). The Incas knew many tubers that were very important as food plants. All these plants, among which are potato, *oca* (*Oxalis tuberosum*), *maca* (*Lepidium meyenii*), *ulluco* (*Ullucus tuberosum*) and *añu* (*Tropeaolum tuberosum*), were also applied in medicine. About the economic aspects of these plants an excellent internet source is available (<http://www.nap.edu/books/030904264X/html/>).

Procreation and Plants

A number of plants were used to modulate fertility, or to induce sterility. The use of plants was mostly combined with magic. Among the plants that were applied to induce fertility were the

cabega, the *vilca* (*Anadenanthera colubrina*), the *espinco* (*Medicago hispida*), and the *mocomoco*. Murua (1987, p. 435) states in a general way that the Indians used many plants and potions, not only to procure fertility, but also to induce sterility. In a society where having children was important, the administration of sterility-inducing plants was a severe crime that was punishable by death (Casas, 1939, p. 147; Elferink, 1999). Because those who induced sterility saw few reasons to be communicative, the chroniclers write in general terms about it and give no concrete names of plants. A colonial source reports that the Peruvian Indians considered the consumption of an infusion of the leaves of the *sogue* (*Salix humboldtiana*) a means to cause sterility in women (de Losa Avila y Palomares, 1983, p. 110). It is noteworthy that the Incas used the plant for several medicinal purposes, but that for these applications the infusion of the leaves was not taken orally.

Both plants and magic were applied to increase or to decrease libido (Elferink, 2000). Acosta warned that the excessive consumption of *uchu* or *ají* (chili pepper, *Capsicum annuum*) by youngsters was undesirable, because of the aphrodisiac action of the plant (Fig. 5). This pepper was applied frequently to spice meals. Its use was so common that abstaining from consuming *ají* was considered fasting. Other plants described as an aphrodisiac were the *cuchuchu*, the *siaya*, the *tocoracas* and the *itapallo*. The *añu*, presently better known as *mashua* (*Tropaeolum tuberosum*), has been described as an anaphrodisiac (Cobo, 1964, p. 171; Garcilaso de la Vega, 1966, p. 501). The Inca ruler gave the roots of the plant (it is an important food plant) to their soldiers as food, so that they forgot their wives. A later source describes the plant as an aphrodisiac (de Losa Avila y Palomares, 1983, p. 133). From the plant called *pencácuc* (*Mimosa* sp.) a male and a female form existed. Cobo describes the aphrodisiac properties of this plant, and he states that only the roots of the male form of the plants were stimulating; the roots of the female form had the opposite effect. A comparable peculiar difference between the male and female form of a plant has been ascribed to the *chutarpo*

Ethnobotany of the Incas, Fig. 5 *Capsicum annuum* or chili pepper was an important food plant. It was considered a medicine and also an aphrodisiac

(or *huanarpo*). The male form, *huanarpo macho* (*Jatropha macrantha*), was known to act as an aphrodisiac. The female form, *huanarpo hembra* (*Cnidoscolus peruvianus*), acted in the reverse way, and could be used as an anaphrodisiac to annul the effect of the former (Santa Cruz Pachacuti, 1992). Although the effects of these plants have not been investigated, the description suggests that the plants possessed a magic action rather than a real one. However, in contemporary folk medicine the *huanarpo macho* is still used as an aphrodisiac for men, while the *huanarpo hembra* is considered an aphrodisiac for women and a desaphrodisiac for men (Brack Egg, 1999, p. 145). The *maca* (*Lepidium meyenii*) is a plant that has gained a lot of interest in recent times because of its supposed aphrodisiac and other properties. Because it can stand low temperatures, it was a favorite food plant of high altitudes. Descriptions about its use as an aphrodisiac in ancient Peru are scarce. Cobo, (1964, p. 4-XVI) suspects that the relative

increase of the population in the province of Chincha-cocha was due to the “hot” properties of this plant.

Magic Plants

Plants-Religion-Magic

A few plants played roles in Inca religion because they were used as offerings. Coca and tobacco were most frequently used (Fig. 6). Much information is available about coca and the Incas. The plant was important, but mainly for the upper social classes, because common men were not permitted to chew coca except with the ruler’s permission. In some regions the *espingo* was frequently used as an offering (Arriaga, 1968, p. 211). In many burial mounds of the Chimu (the Chimu kingdom was conquered by the Incas) strings of espingo seeds have been found. Priests used espingo in chicha to get very drunk, suggesting that the plant had psychoactive properties. The identification of the plant is not certain. In an indirect sense maize was the most important plant in religion, because chicha prepared from maize was used by all important and not-important ceremonies as an offering. Furthermore, maize was the basis of *sanco*, a kind of dough or bread that was used in religious ceremonies as a kind of communion.

Maize, coca and potatoes were so important that figures were made from them. These were called *saramama*, *cocamama*, *papamama* (or *axomama*), respectively, and were venerated as objects with supernatural powers. The veneration had a practical background: it was meant to have a good crop of the product from which the figure was made (Albornoz, 1988, p. 165; Arriaga, 1968, pp. 200, 204, 205, 273). The religious importance of these plants is probably connected with the appreciation that the Incas had for these plants: coca as a psychoactive plant, and maize and potato as important food plants. In addition, all three plants were used in medicine.

Divination

Some plants played a decisive role in Inca divination. To obtain an idea about the importance of

Ethnobotany of the Incas, Fig. 6 Tobacco was considered a medicine rather than a recreational drug. Two types of tobacco were used. The wild tobacco was probably identical with *Nicotiana rustica*

divination in Inca society we only have to look at the different types of diviners described by the chroniclers: more than 50 Quechua names are reported. The absolute number of diviners was also very large, as indicated by Acosta (1954, p. 172) and others (Morua, 1946, p. 72; Relación de los Agustinos, 1992, p. 8) who simply state that there were innumerable diviners. Cobo confirms that there were many diviners of several types (Cobo, 1990, pp. 160–163). In every town there were many of them, a statement that earlier was also made by Cieza de Leon (1962, p. LV). Citing another source, Cobo gives the figure of 475 people in Cuzco who had no other occupation than just divining. Intuitive divination was among the principal types of divination, and was often mediated by oracles in the form of *huacas*. A number of (mostly psychoactive)

Ethnobotany of the Incas, Fig. 7 A number of psychoactive plants were used in divination practices. Among these was the *vilca* or *Anadenanthera colubrina*. Vilca was also the name of certain idols. Here the Inca ruler talks with the vilcas and huacas

plants were applied to facilitate contact with the supernatural. Diviners called *yacarcaes*, who recruited spirits from fire, took coca leaves. They pronounced spells with which they summoned the spirit of the person from whom they wanted information. After a few other rituals the “devil” (as the chroniclers describe it) came and without being seen spoke to the attendants. He told them that he was the spirit of the person to whom they wanted to speak (Cobo, p. 169). The procedure was followed in divinations where potential dangers for the Inca ruler or the empire were determined. That could be threat of rebellion or a plot against the Incas. The procedure resembles the one that was used by Inca sorcerers in love affairs. Here tobacco in combination with coca was applied. The person who wanted the

love of another went to these sorcerers with a piece of clothing of that person. The sorcerers used coca and tobacco to get into a trance and raise the spirits of persons who had to become the beloved one.

Vilca (*Anadenanthera colubrina*) was very popular among diviners, who consumed the drug in the alcoholic beverage *chicha* (Cobo, 1990, p. 169), to get intoxicated and attain the right psychic condition to make divinations (Fig. 7). According to Acosta (1954, p. 172) *vilca*, alone or in combination with *chicha*, was applied for all types of divinations. Among the questions which had to be answered, were predicting future events such as the outcome of certain enterprises, whether one would stay healthy or become ill and die. Another purpose

was to find stolen or lost goods. For the same purposes the *achuma*, now better known as San Pedro cactus (*Trichocereus pachanoi*), was used. Murua has described the divination ceremony.

To perform these superstitions and divinations they locked themselves in a house that was closed from within. There they started to drink and to get intoxicated until they lost their senses, and after a day they gave answers to the questions. To reach this effect they smeared their body with certain ointments. The sorcerers first talked with the devil in an obscure place in a way that the people heard a voice, but did not see who talked. They performed many ceremonies and offerings, and answered the questions with yes or no, as they liked it. For this purpose they used vilca or achuma (Morua, 1987, pp. 432–434).

Currently some other psychoactive plants such as *ayahuasca* (*Banisteriopsis caapi*) are used in divination, in addition to those mentioned before. It is not sure however, if ayahuasca was used in Inca times.

Ethnobotany: Malay Ethnobotany

Is There Such a Thing as Malay Ethnobotany?

Rohani Longuet

It is surprising that in a country as rich in floral species and knowledge as Malaysia, Malay ethnobotany – the knowledge that the indigenous Malays have of their flora – has not been studied as such. Lists of plants and their uses have been compiled, but not many systematic approaches on the perception of the flora by the local inhabitants have been made. That is probably because of the diversity of influences to which the country has been submitted through history. Complexity may be perceived as a lack of unity.

One must distinguish between the Malays living in Malaysia and the rest of the “Malay peoples” who have inhabited not only the Indonesian archipelago, but also areas from the Pacific to the Indian Ocean, from Madagascar to New Zealand and Taiwan. It is possible to cover the subject by considering the particular heritage of the Malays that are presently living in Malaysia. These Malay groups have developed a common indigenous system of botanical knowledge. Their system refers to a worldview and a perception of nature that is steeped in the great Asian traditions, but has a particular local terminology and an indigenous use of native – or imported – species. Such an enterprise is useful because, together with the other Malaysian citizens of various ethnic origins, the Malays of that country have to face the problem of the possible disappearance of their natural and cultural heritage.

Malaysia's Botanical Richness

Malaysia is located at the heart of the Indo-Malesian system, one of the biggest rainforest systems on the planet. Rainforests are defined as “evergreen, hygrophilous (living or growing in

moist places) in character, at least 30 m high, but usually much taller, rich in thick-stemmed lianas and in woody as well as herbaceous epiphytes (Epiphytes are plants that grow on other plants mainly for support. Examples of these in tropical rainforests are orchids and ferns. Epiphytes are sometimes also known as “air plants.”) (Shimper 1903, in Dunn, 1975). Diversity, splendour and luxuriance characterize the original flora of the country.

Malaysia itself is divided into two parts separated by a shallow sea. The West part comprises the Southern Malay Peninsula, and the East part comprises the Northwestern part of the island of Borneo. Almost 95 % of the plants present in Borneo and Sumatra – which belong to the same geological area – are present in the Peninsula, a significant feature for the permanence of botanical knowledge among migrating peoples.

Both parts of the country have a “main range”, a series of hills culminating at 2,187 m in Gunong Tahan for the Peninsula and 4,094 m in Mount Kinabalu for Borneo. From the hills, streams run down on limestone boulders to merge in majestic rivers that end in large estuaries where villages have settled. Up until the 1960s, forest covered 85 % of the soil (Polunin, 1988). A relatively small country, Malaysia has a rich density of species: 8,000–10,000 (compared to, say, 11,000 in India). Botanist Keng calculated that the Malaysian flora has 2.96 % of the gymnosperms and 2.79 % of the angiosperms of the world.

- Three factors have contributed to the floral richness (Deverre, 1985).
- The climate, which is hot and humid, with rain all year round;
- Geological stability from the beginning of the tertiary; and
- The encounter and interpenetration, in the Peninsula, of two kinds of flora, from the Asiatic continent in the North and Malesian flora from the South.

Various floral landscapes create a rich pool of environmental resources for the inhabitants to draw from. There are mountains, hill forests,

lowland forest, fresh water swamps, coastal beaches, saltwater swamps and agricultural lands.

The major botanical families are

1. The Dipterocarps. They are so large that a *cengal* tree in the state of Terengganu needed 11 men to circle its girth.
2. Palms. There are five times the number of native palms than in all of Africa.
3. Eugenias. They align the hill slopes with the bright red of their young leaves
4. Tall gingers, mostly strongly scented.

Malaysia is also home to half of the world species of *Nepenthes*, who digest insects in their receptacles, and to other botanical stars like the *Rafflesia Tuan Muda*, the world's biggest flower, many species of orchids and prehistoric species like the *Gnetum gnemon* and the giant fern-looking *Cycas*.

The Geographical and Historical Components of the Malay Knowledge of Plants

The botanical lore of the Malays reflects the Peninsula and Borneo's floral composition. But Malaysia was at a crossroads of maritime routes that brought in science and culture from three great civilizations: India, China and the Arab world.

First were the years of early trade. The people of the Peninsula collected and sold the fragrant *gaharu* (*Aquilaria Agallocha*), dammars (from various *Dipterocarpaceae*) and camphor (from *Dryobalanocarpus camphora*); this trade was recorded in the Chinese chronicles (Weatley, 1980). The Peninsula remained for centuries within the sphere of influence of the Indianized empires, Funan, Sri Vijaya and Majapahit. Its inhabitants may have benefited from early initiation to Ayurvedic botanical knowledge. Some common village native plants like *gandarussa* (*Justicia gandarussa*) and *patarwali* (*Tinospora crispa*) still bear Sanskrit names.

From China came Buddhist scholars. In the wake of Admiral Cheng Ho, a Chinese

community settled in Malacca. Chinese *sen seh* and settlers established medicinal gardens around temples and houses, sharing knowledge on small tropical herbs such as the *empedu bumi* (*Andrographis paniculata*) (also an Indian plant) *getang* (*Spilanthes acmella*), and the *pegaga* (*Centella asiatica*).

Malays have also benefited from Arabo-Persian medicinal and botanical knowledge that included the value of spices as medicine as well as food flavouring and preservatives. They brought in plants names such as *limun*, *henna* and *halba*.

There was a permanent influx of visitors and settlers: from the South – Achenese, Minangkabau, Javanese, and Bugis; from the North – Pattani Malays and Chams, carrying Chinese, Vietnamese and Cambodian knowledge. For instance, Mohammed Yusoh is a well-known roots and leaves seller from the East Coast of the Peninsula. He claimed to have had Arabic, Javanese and Chinese “gurus.” He was also so familiar with some aboriginal tribes that he was dubbed “Mat Sakai” (Mat of the aborigines). The term *Sakai* has since become derogative, and is now replaced by *Orang asli*, literally the “original people.” The life source of the *orang asli* tribes is the forest. They are the ones who would have transmitted knowledge on dangerous species like the *Antiaris* dart poison, the *tuba* Derris to kill fish or the *susu harimau*, a contraceptive mushroom.

Like pharmacists, aboriginal people provided the medicines; like medical doctors, Malay *bomoh* or traditional healers would tune the prescriptions to their patients. Some Malay peoples – proto – or deutero – Malays like the Jakun – belong to the *orang asli* group. However, generally for the Malays, the forest is considered dangerous. It is a vast, inexhaustible store of resources to be exploited. Villagers on the forest fringes, hunters, martial art gurus, herbalists and animal traders make expeditions in the forest from the base of their village.

One difference between the forest dwellers and the Malay settlers is the level of intervention that the Malays have introduced in nature. They tended to select and “grow” their natural environment in settled villages while aboriginals made

use of everything they needed on the large tracks of forest they knew, without changing the natural composition of species. Malay villagers encouraged the growth of *nipah*, *nibong*, *pinang* and coconut palms. They planted crops on the outskirts of their villages and fruit trees around their houses.

Another example of a transmitter of botanical knowledge is Tuk Ku Paloh – Syed Abdul Rahman (1818–1918), a religious teacher of Arabic lineage and a political advisor to three successive sultans of Terengganu. He planted orchards of *jambu* (*Eugenia* sp.) and *rambutan* (*Nephelium* sp.) fruit trees in his vast ashram-like compound. He even created a spice garden for medicinal use.

Species native to drier and cooler regions were acclimated. In the Northern states, a *Zyziphus* (*bidara*) used in religious rites (also belonging to the Chinese materia medica) is planted around mosques and cemeteries. The pomegranate, dear to Arabo-Islamic tradition and a symbol of fertility for the Chinese, is grown in some Malay gardens against climatic odds.

Concepts and Philosophy of Malay Ethnobotany

Researchers have been puzzled by the apparent contradictory and overlapping beliefs of the Malays. A traditional healer would summon spirits from the animist past, chant a Hindu mantra, wrap up the incantation in a Muslim *doa* prayer and prescribe a plant preparation. The Malays do not seem to have perceived a contradiction in their multi-layered spiritual interpretations of the relationship of man with nature.

Mohd (1995), writing about the passage from animism to Hinduism, suggests that the Malays “merely transferred their beliefs in spirits and in nature to the various Hindu gods.” Subsequently, one could surmise that the belief in Shiva, a Hindu creator god, introduced the concept of a unique force behind nature, separate and above it, perhaps preparing for the Muslim concept of *tawhīd*: the oneness of God.

During the nineteenth century, compilations of medicinal and botanical knowledge were made in *jawi* script or translated, giving lists of therapeutic plants. These, like the *Tajul Mulu* (Medical Book of Malayan Medicine) or the *Ilmu Tabib* contain lists of charms and references that place them in traditional healing systems. The role and the effect of the plants were described according to their relation with the balance between the four elements, the humours and “hot or cold” or “wet or dry” states. Studies are still needed to identify to which tradition(s) they actually owe their formulas.

Today, the idea of an indigenous perception of nature – how the Malay villagers see themselves in relation to the plant world – can be found in interviews with villagers and forest workers, especially in remote areas. They have a strong sense of a reciprocal link between all living things as *insan* (creatures of God). “The growth of trees toward the sky is their prayer to God,” explained an elderly lady. Plant collectors in the forest believe in the “signature doctrine.” Just like the *Qurʾān* Holy Book, nature is knowledge revealed (*ilmu naqli*).

Villagers have long maintained a symbiotic relationship with nature. Plants are found everywhere in art and crafts; twirling *Cucurbitacea* and Ipomeas are found on carvings on *cenggal* wood verandahs (Said, 2000). Flowers enliven the batik sarongs worn by the villagers. In *pantun* poems (Daille, 1990), fragrant flowers of jasmine and *Michelia cempaka* decorate love promises. In cemeteries sweet smelling *Plumeria* species alleviate sadness. The Muslim paradise is pictured as a garden, so gardens also have religious significance. Even today, the Malays try to arrange some flowers to compose a welcoming entrance to their house (Nor, 2003).

Malay Classification and Exploitation of Botanical Materials

In the vernacular system, plants in general – herbs, shrubs, climbers and epiphytes – are *pokok* (which means “tree” – in lay language). The “trees” are subdivided into *akar*, which means roots and

climbers, *rumput* (herbs) and *paku pakis* – “nails” – for ferns.

The Malay floral nomenclature is pragmatic and empiric. It does not refer to a phylogenetic organization of the floral kingdom; nor does it refer to Arab, Indian or Chinese classifications. Plant species receive their names by reference to their aspect (morphology) or their use (ergology/phytopharmacology) (Table 1).

A name sometimes evokes both aspect and use. *Tongkat* is “cane.” In *Tongkat Ali*, it refers to the aspect of the straight growing *Eurycoma*, a shrub with a deep, hard-to-dig root. The word indicates the use: like a cane, it supports failing strength. *Putar* means “to turn” in Malay and Sanskrit. *Patarwali* (*Tinospora Crispa*) is a spiralling climber. That name is also pronounced *putrawali*. *Putra* means “son”; *wali* is “representative.” So the *Tinospora* in Malay is “the whirling plant that helps to get a male descendant.” The pretty *Tetracera* climber is called *mempelas* – sandpaper – as its rough leaves are used to polish wood and metallic surfaces.

There are also specific species names, sometimes derived from the ancient Malay or Melano-Polynesian vocabulary. For instance, the sea Hibiscus is *Bebaru* from the island of Madagascar.

Composite plant names are formed by adding a qualificative identifying the individual species within the vernacular genus: *Limau* is for citrus, *limau purut* is *Citrus hystrix* and *limau nipis* is *Citrus aurantifolia*. A qualificative may indicate the degree of effectiveness of the material, either as a timber or medicine. *Tongkat Ali* is “Ali’s own cane.” Ali’s name, the Prophet Muhammad’s cousin, carries a connotation of effectiveness and strength. Other tonics for men are associated with Ali. Plants good for women refer to Fatimah, the Prophet’s daughter.

Evocative qualificatives are drawn from the animal kingdom: elephants, bear, tigers, monkeys and buffaloes help characterize plants. The aerial *Paku langsuiyir* is the “vampire fern” – an *Asplenium* which hangs its large and long dishevelled leaves on the fruit trees at the back of a house. Information on location, origin or gender is frequent: “Female” often means a

Ethnobotany: Malay Ethnobotany, Table 1 Examples of forest species familiar to the Malays and their vernacular names

Malay names	Translation	Botanical name	Reputed traditional use
Gajah beranak	Elephant giving birth	Goniothalamus	Post partum decoctions
Penawar hitam	Black medicine	Schortechinii	
Tongkat Ali	Ali's staff, sky pointer	Eurycoma longifolia	Febrifuge, sexual tonic
Teja lawang	Specific name	Cinnmonum	All medicinal decoctions
Aji Samat	Haji Samad	Jackia ornate	Tonic
Tengkok biawak	Neck of monitor lizard		
Betek hutan	Forest papaya	Renellia sp.	Nasal and sinus troubles
Setawar hutan	Forest antidote	Costus speciosus	Mostly decoration
Dedawai	Wiry one	Smilax callophyllum	Tonic, diuretic
Tongkat Ali	Ali's staff		
Kacip Fatimah	Fatimah's scissors	Labisia pointiana	Feminine health
Kerbau melawan	Fighting buffalo	Shefflera sp.	Sexual tonic
Gajah tarik	Pulling elephant	Strychnos intai	Tonic, hypotensor
Hujung atap	Tips of roof thatch	Baekia fructescens	Postpartum
Mas secotet,	A spot of gold	Ficus deltoidea	Tonic for women
Telinga kera	Monkey's ear		
Tonkat Ali biru	Blue Ali's staff	Polyaltia bullata	Heart tonic
Cengal	Specific name	Neobalanocarpus heimii	Mostly building material
Resdong	Nose inflammation	Ervatamia	Nasal and sinus troubles
Telinga beruk	Bear's ear	Thothea	Diarrhea, colic
Mengkudu bukit	Hill Morinda,	Renellia speciosa	In medicinal decoctions
Ginseng Melayu	Malay ginseng		
Akar sarsi	Sarsaparilla	Cinnamomum ebracteum	Fragrant, diuretic

large variety and “male” a smaller one (noted by British forester Watson as early as 1928).

Like the *limau*, some plants names correspond a to modern botanic genus: *Uncarias* are *kekait*, some *Eugenias* are *kelat*, a word referring to the tart taste of their wood. The edible *Eugenia* are *jambu*. *Cinnamomun* species are known as *teja* with various qualificatives: *jantan* (male), *bulu* (hairy). The more poisonous ones are often called *medan* and may be used as insecticides. Misleading appearances or similarities are signalled by a repetition: *Annonacea* are *pisang pisang* – false bananas or the qualificative *hantu* (ghost).

Some plants are so specific to some ailments that they are called by the name of what they cure: there is “ring worm medicine” (*Cassia alata*) and the “sinusite trees” (*Ervatamias*). Or they may be known by the illness they cause. *Excoecaria agallocha* (*bebuta*) is the “blinding” or “blind one” because of its latex, which is harmful for the eyes.

Plant collectors and healers are familiar with the principal names and the alternative names of the most famous floral species. The confusion of species perceived by botanists as they noted the existence of synonyms and substitutes is not relevant within the pragmatic system that gives priority to the use of the plants. Plants that share the same use and same look will be designated with the same names. For instance, leaves from the *Leucopogon Malayanus* – an *Epacridacea* – may conveniently replace the other similar looking *Cucur atap* (roof leaves) species, *Baekia* and *Leptospermum*, in the herbalist post-delivery tea (Yusof, 1985).

As the main criteria for designating plants is their use, a few very useful and well-known species change names. *Oriza sativa* is rice (*nasi*) in the plate, *beras* in the shop and *padi* in the field. *Aquilaria Agallocha* is the *tengkaras* timber of the foresters, the *chandan* tree of collectors and becomes *gaharu* when the precious fragrant wood is found in the tree.

The vast range of use of plants in Malay ethnobotany run from the rites accompanying protection ceremonies to the criminal use by thieves sending *Datura* smoke through the floor boards of houses on stilts. There are building materials, dyes, mats, food, flavourings, wrappings and cosmetic, soaps, talcum, perfumes – a complete shopping mall (Table 2).

Coherent, pragmatic and didactic, the Malay system of vernacular botany was based on the villagers' needs. About 20 years ago Malay gardens in villages were good illustrations of the familiarity of their owners with the local flora (see Extra: "Plants on a Day in a Village 20 years ago").

The Future of Malay Ethnobotany

Today, Malay vernacular botany shares the fate of other ancient knowledge in the world. It vanishes because it is written on vanishing material supports. One of these supports is the memory of the elders. Records have been made and translated into modern Malay and scientific botanical terminology; the most recent are those of Pr. Kamarudin Mat Salleh at the University Kebangsaan Malaysia and of Pr. Roland Werner at the University Malaya). However, behind the names, has the frame of mind and the worldview of the indigenous botanists been documented enough? Can translation render the esoteric yet powerfully suggestive context? The second support of botanical knowledge is the flora of Malaysia. In the process of development, the diversity and quantity of plants species are reduced. In consequence "hands on" knowledge of species which were previously common is on the way to being lost.

On the other hand, the relationship of the Malays with the world of plants still runs deep. Beyond the country's political and scientific interest for biotechnology (see extra "Three Malaysian Plants in the Hall of Fame"), it has been found (Nor, 2003; Said, 2000) that modern Malays grow species from their past in the small gardens of their suburban terrace houses. They have a desire to continue combining esthetics, ethnic heritage and function, in the plants they display in their new environment.

Extra: Plants on a Day in the Village, 20 Years Ago

In the Malay village, a young mother woke up on her mat made of *Pandanus*, with the smell of the *Euphorbia* ambers still warm under her special post-delivery sleeping platform. There was a light fragrance from the surrounding *belukar* secondary forest: the astringent *Rutacea Glycosmis*, frothing *Cinnamomum* and camphor. These contained plants prepared for her morning bath. Her newborn had his umbilical cord cut with a ► *bamboo sembilu* and later he would be circumcised with same type of disposable knife.

The mother is having a breakfast of sweet potatoes sprinkled with grated coconut. She will take a tonic *majun* pill made mostly of spices and ginger (*rempah ratus*) mixed with honey collected from nests on the gigantic forest *Compassia* tree. She set aside a large basin of *ubat periok*, a decoction based on *akar kayu* (jungle roots and trees) bought from herbalists at the market (*Annonacea*, *Cinnamomum*, a bitter *Eurycoma*, the slim leaves of *Baekia frutescens*, and a modest beach creeper, *Vitex trifolia*).

The forest smell pervades the house built in cool timber (*seraya* or *cengal* Dipterocarps) with a *nipah*-thatched roof. The midwife performs a thorough massage of the young mother with coconut oil, applying lime juice on her stomach, wrapping her in a tight batik (dyed cloth) corset and finally applying the heat of stones wrapped in large *Morinda* leaves to help the recovery process.

Meanwhile, the men are at sea on a *chengal* made boat. The sails are made of *sekecut* sedge from the paddy fields mounted on bamboo battens from the *belukar*. They pull ropes made of coconut husks and prepare a *gala gala* caulking made of jungle resin and *minyal kuin* oil in case the deck needed it. The seams on the flanks of the boat rarely leak as they are built with strips of the bark of tannin rich *gelam Melaleuca leucadendron* (from the swamps) fixed during the construction on the *pasak* "nails" *Mesua ferrea* (from the forest) that join the planks of the boat. If a new crew member became seasick, he could use an oil distilled from the leaves of the same *gelam* tree.

In the village, in the afternoon, sitting on a platform in the garden, the great grand mother is sewing a pillow stuffed with floss from the *kekabu* tree. Her daughter gathers *ulam* greens and *daun serai* (*Cymbopogon*) to perfume the sauces for the next meals. A group of young girls ask permission to take some *inai* leaves from the Henna tree for an elder sister who is going to be married soon. She may look at the *bidara* (*Zyziphus*) and the cotton tree which are used during the funeral rites. A small *jambu* (*Eugenia*) has been planted where foetal membranes of the new grandson are buried. Life stages are written in the garden around the elderly lady. The presence of the plants helps preserve practical knowledge as well as spiritual beliefs. The next generation naturally learns from them.

Extra: Three Malaysian Plant Species in the Hall of Fame

A Criminal Tree?

Recently, for as long as 6 weeks, a battle was fought in the news (*Utusan Malaysia* November and December 2004) around a *Rubiaceae* species, the *Mytragyna speciosa* (*ketum* in Malay). Journalists reported that police officers had felled an old *ketum* tree in Perak, causing a stir among nature lovers. The police explained that villagers had called them as the tree attracted drug addicts to the area. In fact, the police in Terengganu had previously felled hundreds of them. Addicts use the leaves of *ketum* to calm the effects of their drug craving, as it was explained in other articles. The tree is placed, just as in Thailand, on the list of forbidden substances.

The *ketum* or *biak*, endemic to Northern Malaysia and Southern Thailand, was traditionally used by villagers in post-partum teas to ease afterbirth pains and by workers who faced long hours of work in the forest. A few times in the past, it had received attention from researchers in Malaysia and abroad. Other species of *Mytragyna* grow in Africa; they have been studied for their alkaloid contents and are used there in traditional compound medicine for mental illness.

Malaysian scientists agreed that the plant did have a potential as a methadone substitute and that it had a mild analgesic effect. It acts on opiate sensitive receptors in the brain.

Researchers at Chiba University in Japan (*Journal of the Pharmaceutical Society of Japan* October 2003) have published analyses on plants gathered in Malaysia and Thailand. Among the newly identified compounds, one of them, a mytragynine pseudoindoxyl, was found to be much more effective than the same amount of morphine.

Tongkat Ali, the "Malay Viagra"?

This shrub or small tree with a particularly thick, deep and straight root is not easy to collect. It used to be very common on the slopes of forest hills in Malaysia. It is also found in Indochina and Indonesia. But now it is becoming rare, and forest officers mark trees because their fame as a source for a sexual tonic has triggered harvests of commercial proportions.

The bitter tongkat or *Eurycoma longifolia* was studied at Malaysian universities and found to be effective, as traditionally claimed, as a febrifuge (a substance that lowers fever) and anti-diabetic. It has a testosterone-like effect on mice, which produce a plethora of male progeny. It does not seem to have harmful secondary effects. Under Malaysian law, it is on the list of protected and non-exportable species.

With academic endorsement, and following Good Manufacturing Procedure (GMP), entrepreneurs in the country are now using extracts of tongkat Ali in very successful "power" drinks together with coffee and ginseng. To face the oncoming shortage of wild material, the *Eurycoma* is now grown commercially.

Sarawak Tree in the Race to Find a Medicine for AIDS

During pharmacological screenings for anti-cancer activity of medicinal plants from Malaysia, a team of US scientists identified an interesting substance in a species of *Calophyllum* (*bintangor* in Malay). It had prospects as an immune system booster and even as a treatment for AIDS patients.

The scientists formed a research company and entered into a partnership with the state of Sarawak to create a drug from the particular variety of Calophyllum that had been collected and is not very common. The Government participated in funding the first stage of the research in exchange for returns on the sales of the end product medicine for AIDS.

Calanolide – and other compounds from Calophyllum species – have passed the tests on their effects on the HIV virus, and calanolide is at the clinical phase. But the competition is fierce and it has to be shown to be better than other candidates supported with equally motivated teams. More information is available at <http://www.forestry.sarawak.gov.my/forweb/research/fr/ip/eco/calophys.htm>, “The Calophyllum Story.”

Ethnomathematics

Molly Tun

University of Minnesota, Minneapolis, MN, USA

Ethnomathematics is the study of the relationship between mathematics and culture. It examines a diverse range of ideas including mathematical models, numeric practices, quantifiers, measurements, calculations, and patterns found in culture, as well as education policies and pedagogy regarding mathematics education. “The goal of ethnomathematics is to contribute both to the understanding of culture and the understanding of mathematics, but mainly to appreciating the connections between the two” (D’ambrosio, 1999, p. 146). Ethnomathematics is a new inclusive, pluralistic perspective of mathematics, in this case referring to a great range of numeric traditions and thought beyond that of those practiced in the Western or modern school systems and circulated by professional mathematicians and academics.

Cultural Mathematics or Mathematical Cultures: Permissible Paradigms?

Mathematics as the culture-free or culture-neutral intellectual contribution of Western civilization was first challenged by the twentieth-century scholars attempting to conceive of mathematics within its cultural context and rewrite what had become a single dominant unilateral history of mathematics. Paulus Gerdes identifies the French

psychologist who explored the social origins of mathematics, G. Luquet (1928), and the German mathematician, ethnologist, and pedagogue who had reflected extensively on early mathematical thinking, E. Fettweis, as the first forerunners of ethnomathematics (Gerdes, 1995, p. 19). In 1938 O’Raum is credited as the first scholar to challenge the colonial aims and legacy of mathematics education in Africa (particularly South Africa and current-day Tanzania), proposing a new model of arithmetic based on the students’ tribal context and knowledge base (see Raum, 1938). The scholars R. L. Wilder and Leslie A. White shared a concern with the anthropological explorations of mathematics, which Wilder presented at the International Congress of Mathematicians in Cambridge, Massachusetts, in 1950 and White in his 1947 publication “The Locus of Mathematical Reality.” The mathematician Morris Kline was also one of the initial scholars to establish the connection between mathematics and culture in his 1953 work *Mathematics in Western Culture*, soon followed by *Mathematics: A Cultural Approach* (1962) which also examined non-Western mathematical cultures and methods.

This new perspective on and exploration of mathematics as a cultural product derived from the anthropological ideas regarding culture that emerged in the twentieth century. In his conference presentation (1950), Wilder highlights that it is very uncommon to discuss mathematics in relation to man and his environment in a moment in which the inwardly directed studies of psychology and anthropology had just recently started to gain recognition in the academic world. The conflict (which can trace its origins as far back as the internalist/externalist divide between Aristotle and Plato) impinged on whether or not mathematics was a divine revelation existing outside of man and meant to be discovered or an intellectual exercise existing inside of man and meant to be invented. Whether invention or discovery, mathematics insights were believed to be either a product of one’s own understanding or of divine design, thus neglecting cultural influence. Leslie White, however, is the first to study both arguments of this debate in order to show that culture

is ultimately the generator of all mathematical knowledge. Based on Durkheim's discussion of the relation between "collective consciousness" (i.e., culture) and the human mind, White demonstrates that since mathematics is both outside "man" (conceived as the individual organism) and inside "man" (conceived as the human species), it can be located in no other place but culture – culture being both a man-made construct as well as a mode of life informing all human action.

The Beginnings of Ethnomathematics

These disperse cultural studies of mathematics were further promoted when they were formally considered part of a new social and intellectual ethnomathematical program as introduced by Ubiratan D'Ambrosio in 1977 during a presentation for the American Association for the Advancement of Science. D'Ambrosio is a mathematician and educator from Brazil who has strongly advocated for a more dynamic and multifaceted practice of mathematics. D'Ambrosio's thinking is strongly influenced by fellow Brazilian intellectual and educator Paulo Freire who promoted a *conscientização* that would allow for a more humanistic education stemming from students' personal experiences and appropriate to their own individual circumstances, making education as a matter of social justice and a means for students to have dialogue, develop consciousness, and politicize (*Pedagogía del Oprimido*). D'Ambrosio applied the principles of *conscientização* in order to appropriate the mathematics practices that have become repressed by Western history and its representation of mathematics. D'Ambrosio even goes as far to say that ethnomathematics serves as a step towards peace: "Mathematics is absolutely integrated with Western civilization, which conquered and dominated the entire world. The only possibility of building up a planetary civilization depends on restoring the dignity of the losers and, together, winners and losers, moving into the new. [Ethnomathematics, then, is] a step towards peace" (Greene, 2000).

Trends in Ethnomathematics: Case Studies and Pedagogy

There are currently two trends within ethnomathematics research: a) the investigation of mathematics practices as cultural constructs of "other" societies (as opposed in some way to Western academic mathematics) and b) the political discussions of mathematics pedagogy, autonomy, and implementation in different cultural contexts. This numeric "otherness" has taken various forms, which Gerdes has extensively categorized as indigenous mathematics, sociomathematics, informal mathematics, mathematics in the (African) socio-cultural environment, spontaneous mathematics, oral mathematics, oppressed mathematics, non-standard mathematics, hidden or frozen mathematics, folk mathematics, and mathematics codified in know-hows (Gerdes, 1995, pp. 19–20). Scholars maintain that these particular expressions of mathematical thought have been systematically excluded from formal, academic mathematics but nonetheless abide by the same numerical principles that unite all forms of mathematical expression and merit investigation.

These studies tend to be anthropological or ethnographic in nature, relying on field study, artifacts, and description to determine how numbers are used and valued by cultural groups somehow designated as outside the Western world. Ethnomathematicians generally accept that the discipline is more creative in its methodological approach, going beyond the limits of history and integrating insights from the fields of anthropology, archeology, literature, linguistics, education, and others.

One of the first studies of another culture's mathematics through an anthropological lens is that of Claudia Zaslavsky. After travelling to Tanzania and encountering local mathematics practices, this teacher from New York decided to publish what she stated to be the first "analysis of African culture from the mathematical point of view": *Africa Counts: Number and Pattern in African Culture*. Since this initial study, the last forty years of scholarship has seen a blossoming of anthropological investigations regarding mathematics practices in diverse contexts.

Ethnomathematics, Fig. 1 Litema wall patterns (Lesotho). Geometrical shapes and symmetry are common topics of study in ethnomathematics (Image by Paulus Gerdes)

The ethnomathematician Marcia Ascher published many collections on diverse mathematical practices around the globe and her work entitled *Mathematics Elsewhere: An Exploration of Ideas across Cultures* exemplifies the main topics and geographic locations discussed in the field, including studies of divination, timekeeping, maps, relationship systems, and models in diverse locations such as the Pacific Islands, Nigeria, Madagascar, and India (Fig. 1).

The political and pedagogical trend of ethnomathematics stems from a conscious protest against the colonial structures that imposed and maintained Eurocentric values and number systems. This process involves a recovery of the third world practices denied credibility and space in the public realm. The pedagogical discussions of ethnomathematics operate under the premise that Western mathematics practices have not and are not always the easiest way for a group of people to learn and understand numbers. In addition, these same standardized practices may not address each student's daily needs or particular value systems in regard to counting and calculating. Because the way mathematics is presented to the youth of any culture dictates how mathematics will be used in societal relationships of that very same culture, many scholars are interested in finally scrutinizing the present state of mathematics education in light of its societal implications.

Alan J. Bishop's study *Mathematical Enculturation: A Cultural Perspective on Mathematics Education* (1988) was one of the most extensive

projects examining the connection between culture and mathematics education. This publication is often cited as the source that proposes six universal numeric activities in which all cultures engage: counting, measuring, locating, explaining, designing, and playing. Bishop considers this project a social project and promotes "the kind of mathematical education which will enable that cultural force [of Western civilization as explored by Kline] to be recognized, absorbed, but also evaluated" (Bishop, 6) (Fig. 2).

Future Collaborations and Resources

The International Study Group on Ethnomathematics (ISGEm) (<http://isgem.rpi.edu/>) was created in 1985 to actively discuss and promote ethnomathematics research. Eventually the North American Study Group on Ethnomathematics (NASGEm) (<http://nasgem.rpi.edu/>) was created as an offshoot of the international group and founded the online *Journal of Mathematics and Culture* which explores the intersection of mathematics and culture while explicitly focusing on pedagogical concerns of ethnomathematics implementation in classroom settings. There are similar study groups based in South Africa, Brazil, and Latin America, including The Latin American Network (RELAET) (<http://www.etnomatematica.org/home/>) which brings together scholars from dozens of countries and houses the indexed *Latin American Journal*

Ethnomathematics,

Ethnomathematics of the Inkas

Thomas E. Gilsdorf
Departamento de Matemáticas, Instituto
Tecnológico Autónomo de México, Mexico City,
DF, Mexico

Under the shade of a tree, some women are sitting. They are watching over several children, but at the same time, their bodies are subtly swaying and their hands are busy moving threads. These women are weaving. As they talk among themselves, calculations are occurring: 40×2 , 20×2 , 10×2 , etc. On their weaving tools, symmetric patterns of geometric and animal figures are slowly emerging, produced from years of experience in counting and understanding symmetric properties. The procedures they follow have been instructed to them verbally as has been done for thousands of years, and they follow it precisely, almost subconsciously. In fact, these

women are doing *mathematics*. They are calculating pairs of threads in blocks of tens (10, 20, and so on) and determining which colors of threads must go in which places so that half of the emerging figures will be exactly copied across an axis of symmetry. These women, and likely some girls who are learning from them, are not writing down equations or scratching out the calculations on a notepad. Remarkably, the weaving is done from memory.

Weaving has existed in most cultures around the world, so the events and hence the mathematics in the previous paragraph could occur almost anywhere. In our case, we are going to consider the mathematics of the South American cultural group of the Quechua-speaking Inkas (Incas). As with weaving, we will see that Inka mathematics is intimately tangled with Inka culture.

Before we can jump into the details of their mathematics, we must take some time to understand who the Inkas were and some small picture of what their culture was like. Backing up even further, the first term we must clarify is “Inka,” by which we refer to a collection of many groups who had a common government, religion, and language but were of distinct cultural origins. When we speak of the Inka Empire, we refer to the territory controlled by the Inka from about 1400 to 1560 (CE). The first Inkas started near Cuzco in present-day Peru and persistently moved on neighboring groups, forming an enormous empire that included part or all of Peru, Ecuador, Bolivia, Chile, Argentina, and southern Colombia (Fig. 1).

We have seen that there is mathematical thought occurring in weaving, but as we proceed, we can also observe factors such as geography that may have influenced the development of Inka mathematics.

Geographic, Climatic, and Environmental Aspects of Inka Mathematics

The Inka territory included regions of widely varying geography: coastal desert, high rugged Andes, the Lake Titicaca inter-mountain area,

Ethnomathematics of the Inkas, Fig. 1 The Inka Empire (From D’Altroy (2003). Used with their kind permission)

seacoast along the Pacific, and jungle on the eastern edge of the Andes as they descend into the vast Amazon basin. From pages 24 to 32 of D'Altroy (2003), we can get a glimpse of the situation, by noting that a 200-km trip by air from ocean to forest in central Peru would cross 20 of the world's 34 major life zones. In addition, the Andes range contains many areas that are rugged enough to be inaccessible even by horseback.

In terms of weather, there are numerous, unstable climate and geological patterns such as earthquakes, droughts, floods, and the corresponding effects of periodic occurrences of El Niño.

These geographic aspects indicate several motivations for mathematics. For example, all successful groups in the dry regions had to have some kind of effective water control in the form of irrigation and aqueducts. Next, those in the high altitudes had to have some form of flexible mountain agriculture, such as terrace farming. Moreover, in many parts of the Inka territory, the groups there had to construct bridges to cross deep canyons and difficult mountain areas. In effect, civil and agricultural engineering were crucial elements of survival. Finally, as in almost any cultural group, knowledge of astronomy is important in terms of predicting planting and harvesting seasons, approximating weather changes, and general time keeping. Mathematics is, of course, part of all of these activities.

A Few Relevant Cultural Groups

As alluded to previously, there were many groups that were part of what we are calling the Inkas, and we would like to mention just a few of them. The relevance is that these groups had their own mathematical concepts and practices, and as the Inkas absorbed these groups into their system, they almost certainly made use of some of that mathematical knowledge. A quite complete general reference on the various groups and their interactions with the Inka is in Moseley (1992).

Of the many competing cultural groups in what became Inka territory, we can first mention the

Moche of the northern Peruvian coast, from about 100 to 700 CE. Later, in old Moche territory, a substantial group called the Chimú arose, forming the Chimor Empire with its capital city of Chan Chan. The Moche-Chimú group was the largest Inka rival, and they inhabited the northern Peruvian coast during the Early Intermediate period to the Late Intermediate period (about CE 0–1470). They practiced river valley agriculture along several of the rivers that descend from the Andes to the Pacific, including the Moche River. The Inkas did not overcome them until 1470.

Another group is the Huari of the central Andean highlands of Peru during the Early Intermediate and Middle Horizon periods (about CE 600–1000). The Huari engaged in advanced irrigated terrace farming and had quite mathematical artwork.

Next, we can mention the Aymara kingdoms of the Lake Titicaca region of the Late Intermediate period (about CE 1000–1400). The Aymara themselves consisted of several groups, e.g., the Colla and Lupaqa groups. Also, the Aymara had their own language group, and some dialects of Aymara are still spoken today. The Aymara also had extensive terrace agriculture as well as domesticated llamas and alpacas.

The last of this sampling of groups that we mention is the Nazca of the southern Peruvian coast of the Early Intermediate period (about BCE 400–CE 500). Some indication of Nazca understanding of geometry and astronomy can be seen in the lines and figures they created in the desert. It is still not clear what the lines represent, but there are connections between many of the lines and both astronomy and ritual of the Nazca. The interested reader can get some idea of this topic in the book edited by Aveni et al. (1990) and in the article on Nazca lines in this encyclopedia. Of course, we cannot exit the Nazca topic without mentioning in passing the inspiration to mathematics teachers in the name of Maria Reiche (1903–1998). Reiche was a German-born teacher who made a daring career move in 1932 by moving to Peru. By the end of her career, she had played a crucial role in the preservation and study of the Nazca culture and lines. See her collected works in Reiche (1993) for more details.

All of the above groups had some knowledge of mathematical ideas. The *kipu* [also called quipu, a mathematical recording device of strings and knots] that is discussed in detail elsewhere in the encyclopedia existed long before the rise of the Inkas and was known, for example, to the Huari and Aymara; see chapter 10 of Quilter and Urton (2002). As the Inkas grew to control the territory, their control and/or interaction with these groups must have played into their own mathematical understanding and development. We could even go much farther and say that this little piece on Inka ethnomathematics is only a peek into the larger realm of mathematical interaction, history, and culture of Andean societies, most of which has yet to be carefully researched.

Understanding Preconquest Inka Culture

Tahuantinsuyu, “Land of the Four Quarters,” is the word the Inka used to describe their territory. We would like to know a little about what Inka culture was like before the arrival of the Spanish in 1532. However, it turns out that it is not so easy to reconstruct an ancient culture.

First, although the Inkas were indisputably advanced in many regards, they did not use a writing system as we know it. In fact, the subject of how the Inkas created and maintained complexity in terms of society, government, and economy without communication through what we would consider a writing system is one of active debate. The *kipu* represents a mathematically based system of information keeping that could well have served in place of writing. Meanwhile, however, it is also the case that the Inka groups made use of oral tradition, whereby information, history, and social practices are passed along via oral descriptions. See Schneider (1994) for a general description of oral tradition. Also, an interesting description of Inka culture and literature can be seen in Lara (1960).

Next, there are problems with accuracy of information on the history of the Inkas. Because the only studies of Inka culture we know of took place after the Spanish conquest, information

about the Inkas is either substantially culturally biased, as in the case of most Spanish chroniclers, or is a study of a group that has changed significantly in nature, as is the case in studying present-day descendants of the Inkas. Thus, accurate information is difficult to obtain. For our purposes, two sources considered to be relatively accurate are those of Pedro Cieza de León and Felipe Guaman Poma de Ayala. In Ascher and Ascher (1981, p. 3), the reader may find a detailed description of original works and translations of Cieza de León’s work, and in the bibliography, here we have listed a reference to the works of Guaman Poma (1980) [1614]. Guaman Poma is particularly known for the many drawings of Inka. From sources such as these, we can explain a few aspects of Inka culture that are relevant to our theme of mathematics.

One feature of the Inkas worth mentioning is that as they expanded into regions of other groups, they allowed those groups a certain amount of local control. There are two advantages to this attitude. One is that the subjugated groups would not be as likely to reject Inka rule. The other, relevant to our theme of mathematics, is that by allowing the conquered groups to retain some original culture, the Inkas could use and improve mathematical and engineering ideas of those groups, such as astronomy and agriculture. This last comment implies that some of the mathematics of the Inkas was probably diffused from other groups.

Also relevant to the development of mathematics in the Inka region is that of economy. Starting with very early organized groups and extending even to the present, trade has been an important factor in the societies in the Inka region. In addition, the Inka economy included an extensive taxation system. Later, we will see that this taxation, among other activities, could be recorded on the Inkas’ *kipus*. A good reference to the ideas of trade and interaction of the various groups can be found in Moseley (1992).

Quechua Number Words

Our first mathematically close look at the Inkas comes by way of discussing Quechua number

words, which reflect Inka numeration. In a study of numbers in cultural mathematics, there are two distinct aspects that we must consider: number words and number symbols (representation). These two concepts are not the same.

The first things we must clarify have to do with Quechua, the language used by the Inka. Until the 1960s, it was commonly thought that Quechua originated and spread with Inka expansion. In Mannheim (1985), Mannheim (1991), Stark (1985a, b), Urton (1997), and Weber (1989), the reader may find explanations and references indicating that Quechua in fact originated in northern central Peru and later split into essentially two branches. For our intentions, we take as our model Weber's description of Huallaga (Huánuco) Quechua, which is often referred to as *Quechua I* or *Quechua B* in the references. As Weber indicates, Huallaga Quechua seems to have suffered fewer changes than some other Quechua dialects, which implies that our discussion here of number words should have some accuracy.

Here is a short list of number words from Huallaga Quechua:

Huk, 1; *ishkay*, 2; *kimsa*, 3; *chuska*, 4; *pichqa*, 5; *soqta*, 6; *qanchis*, 7; *pusaq*, 8; *isqon*, 9; *chunka*, 10; *pachak*, 100; *waranqa*, 1000

The format of more complex number words is the following:

[multiplier] {nucleus} (adder)

The nucleus is always a power of ten. For the examples that follow below, we will employ the above notation, namely, multipliers, []; nuclei, {}; and adders, ().

Example 1: *isqon pachak*: [9] {100} = $9 \times 100 = 900$.

Example 2: *qanchis chunka pichqa*: [7] {10} + (5) = 75.

Example 3: 347,002: [[3] {100} ([4] {10} (7))] {1000} (2).

kimsa pachak chuska chunka qanchis waranqa ishkay.

From the number words and the examples above, we can deduce that the Inkas counted in base ten; i.e., they used a decimal system.

Looking Deeper: Weaving, Symmetry, and Counting

The previous section describes some basic facts about number words of the Inkas. However, that information tells us little about the cultural context of Inka mathematics. Such contexts between mathematics and culture entices us into the field of ethnomathematics. Good places to start in the study of ethnomathematics in general are with Selin (2000), Ascher (2002), Closs (1986), Pacheco (1997), Urton (1997), Zaslavsky (1973), and Gilsdorf (2012). What comes out of ethnomathematical considerations is the understanding of how a particular culture perceives and interprets mathematics. It is often surprising to learn that some cultural activity of a particular group involves elegant mathematics that are not easy to see until we look closely and think differently. Moreover, although modern Western mathematical notation of the mathematics being used may not make sense to people of the group, it becomes clear that they nevertheless understand the concepts. The interesting part is that the Western and non-Western interpretations can be dramatically different. We will next examine some such activities for the case of the Quechua-speaking Inkas.

Let us look more carefully at the situation of the women who were weaving, described at the beginning. The first mathematical observation we can make is to notice the symmetry patterns that evolve from the weaving process. In chapter six of Ascher (1991), we find a careful discussion of decoration and various translations, reflections, and rotations that reveal a cultural emphasis of the Inkas on formality, precision, and repetition. Figure 2a–d shows some examples of weaving patterns of the Inka and some other cultural groups eventually controlled by the Inkas. In Fig. 2a, for example, we can observe many types of symmetry. One such symmetry is horizontal: imagine a horizontal line drawn halfway through the figure. Then we see that the pattern in the upper half is exactly repeated in the lower half. Similarly, if we draw a vertical line down the middle of the figure, then the pattern on the left half is exactly repeated on the right half, so the figure has

Ethnomathematics of the Inkas, Fig. 2 Bolivian textile patterns. From Tamara E. Wasserman and Jonathan S. Hill, *Bolivian Indian Textiles, Traditional Designs and Costumes*. New York: Dover Publications, 1981, Plate 17

vertical symmetry. Now let us look at Fig. 2b. Except for slight displacements of some of the smaller parts of the figure, it has horizontal symmetry. It does not have vertical symmetry, however: observe that if we draw a vertical line through the middle of the rectangular spiral part of the figure and reflect the figure across that line, then the spirals will appear in a different orientation. That is, we will not see the same pattern being repeated. On the other hand, the rectangular spiral pattern appears again in Fig. 2c, which, although it does not have vertical symmetry, has rotational symmetry. Imagine putting a tack in the middle of the strip pattern and rotating the figure 180° . The rectangular spirals then appear in the same orientation as in the original unrotated figure. Now let us look at ceramics, namely, the item marked “300” from Fig. 3. It has several symmetry properties including vertical, horizontal, and rotational

symmetry. On the other hand, item 311 of Fig. 3 only has vertical and translational symmetry (translational symmetry means the pattern is repeated if we slide the figure to the right or to the left). Next, item “401” of Fig. 4 only has translational symmetry.

Furthermore, symmetry can appear in contexts other than weaving. If you want to look even deeper into more types of symmetry properties, you can read Ascher (1991), chapter 6.

The above is a good practice for learning about symmetry patterns in general, but we must get back to the cultural part of this. We can ask questions like: What can we deduce from the symmetry properties used in a particular cultural group? In the case of the Inkas, we see the repeated preference for a lot of symmetry. This preference indicates a strong sense of order and precision in Inka culture and mathematics. This corresponds with our general knowledge of the Inkas as being a culture that kept careful records via their *quipus*. Detailed discussions of quipus (quipus) can be found elsewhere in this work, as well as in chapter 10 of Gilsdorf (2012).

Here is another question: how do the weavers know how to construct the patterns in order that they have such symmetry? Even in the case of what at first appears to be a simple shawl having several stripes of varying widths, we can ask as to how the weaver knew how to obtain the widths from the threads. Look at Fig. 2a again. In these questions, we are in fact asking about mathematics. The people (mainly women) who weave such items must in fact count (*yupa*, “to count or account”) threads. For the case of stripes, the number of, say, red threads for the first stripe must correspond in some way to the number of red threads that might appear later in the pattern, so that the two red stripes have the same width. The number of threads to be counted in each step of a weaving process is often complicated and must be decided upon ahead of time. Indeed, the weaver must know in advance what the entire pattern will look like. Once the process starts, what is remarkable is that the weaver does the counting of the threads mentally. A detailed discussion of how groups of threads are counted by Inka (Quechua) weavers can be found in

Ethnomathematics of the Inkas, Fig. 3 Inka design patterns (From Menzel (1976), Plate 26. Used with their kind permission)

chapter 4 of Urton (1997). In our context of ethnomathematics, we can observe some mathematical properties in Inka weaving. One such property described in Urton (1997) (see Fig. 6) is that thread counts are usually done in blocks of 10 and 20 and that in general what is being counted are values of pairs of numbers of threads. Notice the influence of the decimal system. The complex geometric or animal motifs are created by a process called *pallay*, “to pick up.”

Gender and Inka Mathematics

If we go back to the first line of this piece on Inka mathematics, it is a group of women that is involved in weaving. Moreover, it is worth mentioning that Urton (1997) refers to master weavers called *Mamas* (a Quechua word, not the word for mother) who are women who most likely started weaving when they were girls and reached a high level of expertise. They are

Ethnomathematics of the Inkas, Fig. 4 Inka design patterns (From Menzel (1976), Plate 31. Used with their kind permission)

generally treated with special respect within their community. The *Mamas*’ abilities in counting and understanding patterns of symmetry and in geometry are part of that expertise. The ethnomathematical aspect of this situation is this: if we asked one of these women to explain geometric or symmetry properties in terms of lines, rotations, polygons, and so forth, they probably would not explain them in such textbook-like terms. Yet, they clearly understand these mathematical concepts. The difference is that

their understanding comes from the perspective of a weaver who must create a cultural product and who wants to include certain patterns. There is more to say regarding the role of women in society and their skills at mathematics.

It is well known that in Western culture, until recently, women have traditionally been left out of mathematical professions. One famous example from the 1800s is that of Sofia (Sonya) Kovalesskia (Also spelled Kovalessky). Who was the first woman to earn a doctorate in

Ethnomathematics of the Inkas, Fig. 5

Inka design patterns
(From Menzel (1976),
Plate 45. Used with their
kind permission)

mathematics but could only obtain it through the support of male mathematicians (mainly Karl Weierstrass) and was barred from employment in the mathematics departments in several countries afterward. This was because of her gender. Details of the mathematical life of Kowalewskaja can be found in Burton (2007). More details about tendencies in Western culture with respect to mathematics can be found in chapter 1 of Gillsdorf (2012). Thus, the connection between gender roles of women and their skills in mathematics could get overlooked. Indeed, Berlo (1996) indicates, “In the modern Western world, both textiles and women are marginalized. A priori assumptions about textiles and women allow otherwise sensitive investigators to delimit women’s activities...” (438). So, let us discuss some of this within the context of Inka culture.

There is a definite connection between gender and weaving in Inka culture. Costin (1995, p. 69) describes her archaeological work on pre-Inka Wari culture in which she concludes that *all* females spun thread and made cloth. In addition, in her investigation she concludes, “The ethno-historic documents tell us that most cloth was manufactured in a domestic setting and that women were the primary producers of thread and cloth” (68). This indicates a strong identification between being female and textile production, and the identification was already present before the rise of the Inkas. Costin’s findings and supporting documents allow her to conclude that elite pre-Inka Wari women in fact created wealth for their families through their production of spinning and weaving (69–70). In a later work that focuses on gender roles and cloth production

Ethnomathematics of the Inkas, Fig. 6 Warp counts in Inka weaving. From Gary Urton, *The Social Life of Numbers, A Quechua Ontology of Numbers and Philosophy of Arithmetic*. Austin: University of Texas Press, 1997, Figure 4.6, page 121. Used with their kind permission

in pre-Hispanic Inka times, Costin (1998) observes that cloth production continued to be a crucial activity and that Inka royalty carefully chose women to be weavers dedicated to making elaborate cloth. The women attained high social status, though at a high cost of being secluded from society in general and having to remain virgins. Nevertheless, the existence of the selection of chosen women as weavers indicates the importance of cloth production to Inka society and reinforces the importance of female gender identity within the realm of cloth production. This importance of gender and weaving also appears in the work of Guaman Poma in which virtually all of his drawings that relate to weaving

show women as the producers of cloth. See Costin (1998, p. 131) for a good sample of drawings from Guaman Poma regarding cloth production. Hence, we can piece together the connections between weaving, mathematics, and gender to conclude that the mathematical skills involved in weaving (thread counts, symmetry, geometric patterns) were extremely important to the Inkas and that the corresponding knowledge base was almost exclusively connected to being female. Finally, it turns out that connections between gender roles and cloth production can be found in other cultures. Two examples are the Aztecs (see Brumfiel 1996) and the Maya (see Hendon 2006).

Ethnomathematics of the Inkas, Fig. 7

“Birth order” and naming of ears of corn. From Gary Urton, *The Social Life of Numbers, A Quechua Ontology of Numbers and Philosophy of Arithmetic*. Austin: University of Texas Press, 1997, Figure 3.3, page 86. Used with their kind permission

A Bit More About Counting, Pairs, and Even Numbers

In Quechua culture, counting is closely tied to important cultural aspects. Kinship and social organization, as explained by Urton (1997), represent one such aspect. On page 85, for example, he tells us that ears of corn on a stalk are carefully named in the order in which they appear, with the first representing the “mother” and others being defined in accordance to the first as offspring of the mother (Fig. 7).

Note that the order of the counting is as important as the counting itself. As for the subject of pairs, it turns out that the Inkas view the property of being even in a count as extremely important. In fact, we could go so far as to say that odd numbers are considered as incomplete pairs. We saw above that the counting of threads in the weaving process is done in pairs of threads. There are many more instances in which one counts pairs in Quechua society. The perception of even versus odd numbers is in fact one of the main themes of Urton’s (1997) book. The cultural impetus for this viewpoint is that the Inkas constantly strive to have proper order in their world. Such order even extends to contexts like social situations. If a person has done something inappropriate, then something must be done by him/her or by the community so that proper social order is regained. This can be thought of as completing an incomplete pair. By the way, notice that this persistence of order and proper organization appeared in the symmetry patterns, too.

A Few Remarks About Astronomy

Inkan astronomers knew about the solar, lunar, and Venusian cycles. They had a solar calendar and festival calendar based on 12 lunar cycles, plus adjustments to account for the difference necessary to make a full 365-day year.

Throughout the city of Cuzco, there are remains of some of about 400 markers, called *huacas*, along with imaginary lines called *ceques* (also *zeq’*e**). These lines originate from the center of Cuzco. Figures 8 and 9 show some details of the system, though you will have to read chapter 7 of D’Altroy (2002) to fully understand the figures. These *huacas* had ritual and social significance. Some had connections with astronomy, hence mathematics. In particular, the Inka used several of the *ceque* lines as part of astronomical observations such as the June solstice. Furthermore, the *ceques* and *huacas* were crucial components of the Inkan religious ceremonies, and in fact, the *huacas* are more accurately described as sacred shrines.

Astronomy and culture quickly become intimately involved with each other. We know that astronomy and mathematics also have a close relationship, so we can conclude here that astronomy, culture, and mathematics of the Inkas are intertwined.

Yupana

The Inka performed rather complicated computations. The *kipu* was a record-keeping device

Ethnomathematics of the Inkas, Fig. 8 Cuzco's ceque system. From Terence D'Altroy, *The Inkas*. Oxford: Blackwell Publishing, 2003. Figure 7.1, page 160. Used with their kind permission

Ethnomathematics of the Inkas, Fig. 9 Schematic diagram of Cuzco's ceque system. From Terence D'Altroy, *The Inkas*. Oxford: Blackwell Publishing, 2003. Figure 7.2, page 161. Used with their kind permission

not used for calculating. In fact, most of the knots on known khipus are tight, implying that the values on them were usually intended to be fixed. This leads us to ask the question: How did they make the computations? The answer to this question is still not completely understood. One possibility arises in the first of the drawings of khipus made by Guaman Poma.

The rectangular grid of solid and unfilled dots appears to be a kind of counting board; however, Guaman Poma gives no explanation of the grid. Certainly there would be reason to believe that the grid has mathematical meaning because of its appearance with a khipu. A curious aspect of the grid is that each row contains 11 dots, something that obviously does not coincide with a decimal counting system. In addition, because Guaman

Poma's work occurred after the Spanish conquest of Peru, the grid does not necessarily represent a device of the Inka.

On the other hand, proposals of mathematical uses of the grid have been given, with the term *yupana* (Quechua for the verb to count) used to denote it, such as those appeared in Mackey, Pereyra, Radicati, Rodriguez, and Valverde (1990) and Higuera and Clara (1994).

The mathematical methods for counting that are presented make logical sense, such as filling the 11th dot as a placeholder for powers of ten. Included are photos of three-level rectangular stone figures that resemble counting grids in some ways that could have served as abaci for counting. There are descriptions by Spanish chroniclers of observations of Inkas counting on

these rectangular forms, but here we encounter the problem of accuracy. A conclusive explanation of the grids and rectangular forms still has not been given. However, the works cited here point toward possible patterns of counting or symbols.

Acknowledgments The author would like to express his gratitude to a number of people who made useful comments about the paper and/or about the topic of Inka mathematics: Elisa Alcántara G., Professors Alejandro Ortiz F., Clara Lucía Higuera Acevedo, and Professor Gary Urton who looked over a draft of this work.

Faience in Ancient South Asia

Blythe McCarthy

The term faience when referring to ancient materials describes a man-made material of mineral grains, generally quartz or sand, that are bound together by varying amounts of glass, often with a layer of glass (a glaze) on the surface. The material can be very friable and crumble easily or can be hard and dense, depending on the amount of glass present. Several terms have been used to describe this material including glazed quartz frit, glazed paste, glazed composite bodies, blue-glazed whiteware, fritware, and siliceous paste. Faience is however the term most commonly used. Although faience is most often associated with ancient Egypt there was also a well-developed faience industry in the Indus Valley as well as in ancient Mesopotamia. The faience industry in South Asia dates to the third millennium BCE while that from Egypt dates to the first half of the fourth millennium BCE and Mesopotamia from the late fifth millennium BCE (Moorey, 1985; Stone & Thomas, 1956).

Faience using quartz for the mineral grains first appeared in South Asia during the Kot Diji phase (2800–2600 BCE or Nausharo I). It is seen at Nausharo and Mudigak in the form of beads (Barthélemy de Saizieu & Bouquillon, 1997). Beads were primarily small in size and shaped

as cylindrical rings during the early Harappan period, Kot Diji phase; however small tubular, spherical and diamond shaped beads have also been found. There are also beads, lenticular and biconical in shape, from this period at Harappa (Kenoyer, 2000). Some of the faience from the end of this phase appears similar to compact faience seen in the later mature Harappan phase. Beads continue to constitute a large proportion of the faience into the mature Harappan phase (<http://www.harappa.com/indus2/174.html>). There is a concentration of ellipsoidal beads, but larger and more complex beads, such as segmented and multicolor beads, are present as well. Faience beads form a small part of the bead corpus with steatite beads accounting for the majority. At the site of Nausharo only faience beads and small amulets made of faience have been found. In addition to beads, bracelets, buttons, spindle-whorls, gamesmen, animal figures, and small jars made of faience have been found at the sites of Harappa, Chanhudaro, Lothal, and Mohenjodaro among others. Figure 1 shows some fragments of bangle bracelets of varying diameter, as well as vessel fragments. Small faience jars have been found in all faience containing strata at Harappa. Several of the vessels have textile impressions (Kenoyer, 1998, p. 159).

Faience is occasionally found in sites of periods later than the Harappan period. A microbead hoard was found in a black slipped ceramic at the site of Agiabir (Mirzapur), Uttar Pradesh (Singh, 2002) dated to the

Faience in Ancient South Asia, Fig. 1 Compact faience bangle bracelet and vessel fragments from the site of Harappa

Northern Black Polished Ware (NBP) culture (600–200 BCE). Occasional faience beads were recovered in two earlier periods at the site, that of the Narhan culture (1300–900 BCE) and Pre-NBP with Iron (900–600 BCE). Singh states that it was similar to the high strength faience of the Indus Valley civilization. Faience bangles also continue after the Harappan period and may lead to the introduction of glass bangle technology in the early historic period (600 BCE) (Kenoyer, 1994).

Two types of quartz faience have been identified for the Indus Valley Civilization. One, coarse with 50–100 μm quartz grains, is speckled in appearance, with a glass binder and colorant. This material was used for beads and small tokens (Barthélemy de Saizieu & Bouquillon, 1997). A second type is fine with a compact structure, evenly colored with quartz grains less than 30 μm in diameter. This dense, homogeneous form of faience was determined to have been formed by multiple cycles of heating, to a temperature between 1,000 and 1,100 $^{\circ}\text{C}$, and grinding an initial mixture of alkalies (salts), clay, and quartz. This produced faience of uniform color due to a very homogeneous glass phase and very small quartz crystals as seen in Fig. 2. The addition of alkalies in the final step where the objects were fashioned resulted in a thin surface glaze through an efflorescence glazing process (McCarthy &

Vandiver, 1990). In this process, the alkalies migrate to the surface during drying, react with the quartz particles at the surface and form a glass (<http://www.harappa.com/indus3/255.html>). This type of faience manufacturing results in a material of higher strength than other forms which may account for its use in bangle bracelets and vessels unlike the other forms of Indus valley faience which are primarily used for beads. Faience can be manufactured in this manner without the addition of glass, i.e., with only salts and sand; however, this forms a glazed material with a very friable interior.

A workshop was found at the site of Harappa in 2001 (Kenoyer, 2003) that included debris from faience manufacture (<http://www.harappa.com/indus3/246.html>). Steatite tablet molds, carved in reverse, were uncovered as were firing containers, kiln supports and a yellow green slag. The clay containers were lined with crushed bone and steatite. (See slides 250–253 at <http://www.harappa.com/indus3/slideindex.html>.)

To date, no traditional kilns have been found that can be linked to faience manufacture. Recent experiments have resulted in a plausible method for the firing of the small faience objects found in the Indus Valley culture. Replication of the containers, setters and faience material similar to that found in the workshop were made and used to fire faience and steatite. The filled containers were set

Faience in Ancient South Asia,

The *dark gray* grains are quartz, the *light gray* matrix is the glass phase. The exterior of the bangle runs along the lower edge of the photomicrograph and a thin glaze layer is visible along part of the length at the *lower right*

F

in a bonfire. The temperature in the containers reached 935 °C and glazed faience resulted. (See slides 254–257 at <http://www.harappa.com/indus3/slideindex.html>.)

The color of South Asian faience varies. When a pure quartz mineral is used for the grains and there is no colorant in the glass phase a white material results. This may have a colored glaze layer and so appear colored if not broken. If a colorant is present in the glass binding material, such as copper that produces a blue color, or iron oxide particles, that produce a red color, the interior of the faience has that color. When weathered, faience appears similar to weathered glass and the two materials can be easily confused. Colors include white (colored by high calcium), black (colored by manganese), deep blue (colored by copper or cobalt and manganese), yellow, brown and red-brown (colored by iron), and brilliant red. Faience with multiple colors has been used to imitate banded agate and agate or carnelian eyebeads, white with brown, black or red-brown (Barthélemy de Saizieu & Bouquillon, 1994; Kenoyer, 1998). Lead has been found in the glazes of two Indus period faience beads from Nausharo (Barthélemy de Saizieu & Bouquillon, 1995). This is 1,000 years before the earliest known lead glazes, but the small number of beads containing lead may indicate that it was an experiment.

Dayton theorized that spent metallurgical molds made of steatite were used to form the first faience (Dayton, 1989). Bouquillon and Barthélemy de Saizieu identified such steatite faience in four cylindrical beads from the pre-Indus period at Mehrgahr dated to around 3000–2800 BCE where a steatite glazing tradition was in place as early as the Chalcolithic period (Barthélemy de Saizieu & Bouquillon, 1995). This date places the manufacture and use of this material earlier than siliceous faience in South Asia. In this form of faience, ground steatite is used for the mineral grains. The steatite faience makes up less than 1 % of the steatite objects recovered from the site. The compositions of the glazes on the steatite faience are similar to those found for glazed steatite from the pre-Indus period.

The development of faience occupies an intermediate step in the technological progression that led to glassmaking in South Asia. The earliest step was that of heating and glazing of stones (steatite), followed by manufacture of faience, first one of crushed steatite, then of quartz grains, progressing finally to glass manufacture.

The Scope of This Article

This entry summarizes recent advances in our knowledge of the history of farming technology in Amazonia. Although some reference is made to farming as it is practiced in Amazonia today, the focus is squarely on farming techniques of indigenous Amazonians prior to the European conquest. Limited space has led us to additionally restrict the scope of the entry. First, we will concentrate on techniques and material culture, with little attention to sociotechnical systems. As Pfaffenberger (1992) emphasizes, technology alone does not constitute a human population's adaptation to its environment but rather technology in concert with the social coordination of labor. Archaeologists and geographers have

speculated about the sociotechnical systems of pre-Columbian Amazonian farmers, but there is little firm knowledge. Second, we will focus on how farmers managed the land – light, water, soil, and other resources for crops – and much less on how they managed populations of crops and semidomesticated plants and plant communities. There exist excellent reviews on these topics. Work of Posey (1985), Balée (2013), Erickson (Balée & Erickson, 2006; Erickson, 2008), Clement (2006, 2014), and others has sketched out how indigenous Amazonians domesticated landscapes, favoring the abundance of useful trees and other plants and sometimes even extending their geographic distribution (Shepard & Ramirez, 2011). The extent of such landscape domestication, and its impacts on Amazonian forest ecosystems today, are matters of debate (Barlow et al., 2012). Over time, spatially extensive harvesting of wild plants changed to more intensive tending and cultivation and later to crop domestication. Piperno and Pearsall (1998) and Clement et al., (2010) offer useful syntheses of the domestication of plants in the lowland Neotropics and in Amazonia, respectively. For the quintessentially Amazonian crop manioc, work over the past 15 years has shown how farmers' practices shaped, and continue to shape, the traits of the crop (McKey et al., 2012; Ménard et al., 2013; Rival & McKey, 2008), producing great genetic and phenotypic diversity. Work on manioc has also provided scenarios to explain its functional diversification (e.g., in root toxicity in relation to ecological and cultural variation [Arroyo-Kalin, 2010; McKey & Beckerman, 1993; Mühlen et al., 2013; Perrut-Lima et al., 2014]) and its adaptation to different soil types, including the anthroposol created by indigenous Amazonians (Arroyo-Kalin, 2010; Fraser et al., 2012).

This entry focuses on two major themes that have dominated research on how management of the land by pre-Columbian indigenous farmers shaped Amazonian environments, with consequences that can still be observed today. The first of these themes concerns principally forested environments, while the second concerns peri-A Amazonian savannas.

Environmental Constraints, Anthropogenic Dark Earths, and Pre-Columbian Agriculture in Forested Amazonia

An excellent starting point for any article on farming technology in Amazonia is the book by Denevan (2001), an important part of which deals with the agricultural landscapes of forests and savannas of Amazonia and the techniques – the tools, but also the “soft technology” employed to manage soil fertility, weeds, pests, and the like – that shaped these landscapes. Denevan summarizes the ideas, primarily developed by Meggers (1971, 2003), that for several decades formed the dominant narrative of the human use of Amazonian environments. According to Meggers, large farming populations developed only along the major river valleys, where rich alluvial soils of the *várzea* permitted relatively intensive agriculture, supporting dense and sedentary populations. In the *terra firme* between these valleys, the weathered, acid, and nutrient-poor soils allowed only long-fallow slash-and-burn agriculture (swidden) – similar to that widely conducted in Amazonia today – that sustained only sparse, seminomadic human populations. Tracing how these ideas have been challenged by recent work (summarized for broad audiences by Mann (2005)), Denevan reached several conclusions. First, patterns observed today are likely to be very different from those that existed before the European conquest and the introduction of iron tools. When only stone axes (Fig. 1) were available, clearing forest would have been much more difficult than today (Fig. 2). Once a parcel was cleared, farmers would have attempted to cultivate it as long as possible. In Denevan's view, long-fallow shifting cultivation (Fig. 3) – or at least the great geographic extension of this mode of land use – is a postconquest phenomenon, triggered largely by the European introduction of metal tools (cf. Arroyo-Kalin, 2012; Rostain, 2012). Second, although the alluvial soils of the *várzea* are fertile, farming in this environment carries a high risk of complete loss of crops to exceptional floods. Farmers may have preferred to reside

Farming Technology in Amazonia, Fig. 1 Stone axe with a polished cutting edge still used in the 1960s by an Akuliyo group in Suriname (Photo by Stéphen Rostain)

near floodplains and their aquatic resources, rather than within floodplains, and to farm areas with less flood risk, such as bluffs overlooking river valleys. Third, natural constraints to agricultural production in *terra firme* soils – not only those on bluffs, but also those further from rivers – were overcome by environmental changes induced by humans. Where humans lived, the accumulation of kitchen wastes and other detritus added large quantities of nutrients to the soil, as well as large quantities of charcoal. By felicitous circumstance, the chemical properties of charcoal (black carbon) make it a very stable form of organic matter that can functionally replace clay in retaining nutrient cations against leaching (Glaser, 2007; Glaser & Birk, 2012). Long-term human occupation – with short fallow periods and more intensive, fire-dependent, labor-demanding farming – thus greatly modified soils in ways that favored agriculture, creating anthroposol that have been named Anthropogenic Dark Earths (ADE) (Fig. 4). ADEs have much higher nutrient content and nutrient retention capacity than the highly weathered soils from which they were derived.

Farming Technology in Amazonia, Fig. 2 Xetá Indian cutting a tree with a stone axe, Brazil (Drawing by S. Rostain after a photo in Kozák, Baxter, Williamson, and Carneiro (1979))

In this way, even the acid, nutrient-poor oxisols that dominate *terra firme* environments could be converted into soils quite favorable for agriculture. The carrying capacity of farming in *terra firme* is thus dependent not on natural factors, as Meggers argued, but on the interaction between natural and cultural factors. Most ADEs appear to be a legacy of increasing farming populations in Amazonia during the late pre-Columbian period, ca. 2000–500 year BP (Neves, Petersen, Bartone, & Silva, 2003).

Work since Denevan's landmark book has strengthened these conclusions. The distinction between *várzea* and *terra firme* has been shown to be oversimplified, with the recognition of paleoriverine landforms – paleoterraces and paleovarzea – that lie beyond the active floodplain of Amazonian rivers but below the uplands

Farming Technology in Amazonia,

Farming Technology in Amazonia,

Fig. 4 Anthropogenic Dark Earth, or *terra preta*, in the archaeological site of Hatahara on the middle Amazon, near Manaus, Brazil (Photo by Manuel Arroyo-Kalin)

(Coomes, 2004; Dumont, Lamotte, & Kahn, 1990; Irion & Kalliola, 2010; Junk et al., 2011). Books on ADE have proliferated (Glaser & Woods, 2004; Lehmann, Kern, Glaser, & Woods, 2003; Woods et al., 2009). Currently, much work focuses on understanding the occurrence and distribution of ADEs in Amazonia (Bush & Silman, 2007; McMichael et al., 2012, 2014; Schmidt et al., 2014). A particularly important question is whether ADE occurs and is widespread in western Amazonia. In many parts of this region, the absence of a marked dry season precludes the use of fire in forest clearing, and present-day inhabitants often perform “slash-

and-mulch” cultivation, instead of the “slash-and-burn” technique employed today in most of Amazonia (Denevan, 2001). It is currently unknown whether this fire-free (or fire-infrequent) technique resulted in the formation of ADE (McMichael et al., 2014). The “too-wet-to-burn” hypothesis, however, does not hold for a large area of western Amazonia (e.g., most of the Peruvian Amazon below 500 m elevation). This area is little studied for dark earths, and it is too early to conclude that ADE is not widespread (O.T. Coomes, Department of Geography, McGill University, pers. comm.). There are scattered records of ADE from Colombia,

Peru, and Ecuador (Pinedo-Vasquez, Hecht, & Padoch, 2012). Another important current focus is understanding the variation observed among different ADEs. Beginning early in the history of work on ADE, a distinction was made between *terra preta* and *terra mulata*. *Terras pretas* are greatly enriched in charcoal and nutrients compared to neighboring oxisols and contain large quantities of ceramic fragments and other indicators of the proximity of residential sites (e.g., fragments of bones of fish and other animals and other kitchen wastes). Patches of *terra preta* are usually relatively small, from less than a hectare to 20 ha or more, but some reach several hundred hectares in extent. *Terras mulatas* are enriched in charcoal and nutrients compared to oxisols, but not as much as *terras pretas*. Furthermore, indicators of the proximity of residential sites are scarce or absent, and patches often cover large areas, several hundred hectares. Formation of *terra preta* can be explained as the fortuitous consequence of intensive occupation or cultivation, practices of charring organic matter, and the accumulation of various wastes near human settlements. It is debated whether *terras pretas* resulted from continuous occupation over long periods or frequent but intermittent and spatially overlapping short-lived occupations (Arroyo-Kalin, 2012). *Terras mulatas* appear to be associated with larger areas further from villages and were probably burned less extensively. They are less well documented than *terras pretas*, and how they formed is the object of some speculation. According to one hypothesis, *terra preta* arose as a by-product of waste accumulation (“midden model” (Kämpf, Woods, Sombroek, Kern, & Cunha, 2003)). Observing the salubrious effects of charcoal on plant growth in their home gardens, farmers later intentionally tried to reproduce this effect at a larger scale in their farms, for example, by managing fire in ways that resulted in “cool burns” and incomplete combustion, producing less ash and more charcoal (“agricultural model” (Woods & McCann, 1999)). Current work offers little support for the hypothesis that specific techniques were employed to produce *terra mulata*. Instead, recent research tends to support the notion that “cool burns”

were (and sometimes still are) rather generally employed by indigenous Amazonians, in home gardens and outfield farms alike. This work suggests that *terra preta* and *terra mulata* are not different categories, produced by different techniques, but instead reflect a continuum in the intensity of human occupation (Fraser et al., 2011). As locations of villages and their surrounding territories shifted over time, areas nearest the long-term residential-area core developed classic *terra preta*, while areas further away developed soils with less marked anthropic influence. Recent work by Schmidt (2013), building upon pioneering studies of indigenous soil management by Hecht and Posey (1989) and by Hecht (2003), examines how shifting patterns of occupation and location of activities by the present-day indigenous inhabitants of the Xingú River basin generate such a continuum of ADEs.

Since the discovery of the interesting properties of ADEs in Amazonia by archaeologists and soil scientists, research aimed at its applications has skyrocketed. Production of “biochar” is heralded as a way to condition soils, generate biofuels, and mitigate climate change by converting plant biomass into a form of carbon durably stored in soils, thereby reducing CO₂ emissions (Lehmann & Joseph, 2009; Woolf, Amonette, Street-Perrott, Lehmann, & Joseph, 2010). Interestingly, Amazonian farmers have also innovated with “biochar.” In areas of the Peruvian Amazon near Iquitos, increased urban demand has led farmers to increase their commercial production of charcoal, yielding biochar-rich sites for cultivation. This “kiln site agriculture” increases the productivity of the weathered soils, compensating for decreased availability of land and consequent shorter fallow periods in these areas near urban centers (Miltner & Coomes, 2015).

Wetland Agriculture in Seasonally Flooded Peri-Amazonian Savannas

As in forested Amazonia, a late-Holocene expansion – and possibly an intensification – of farming also seems to have occurred in seasonally flooded savannas around the rim of

Farming Technology in Amazonia,

F

Amazonia. In these environments, in addition to acid, nutrient-poor soils, agriculture faces two other important constraints: drought in the dry season and flooding in the rainy season. In the absence of rice or other flooding-adapted crops, one of the ways in which farmers responded to these environments was to construct raised fields upon which to grow their flood-intolerant crops. Here again, the book by Denevan (2001) is an excellent starting point, documenting the occurrence of large complexes of pre-Columbian raised fields in numerous regions of South America, in both lowland savannas and highland interandine valleys. The recent book by Rostain (2012) is another excellent reference.

Raised fields can be defined as “any prepared land involving the transfer and elevation of earth in order to improve cultivating conditions” (Denevan & Turner, 1974). Making raised beds or mounds to serve as planting platforms is a widespread practice of farmers in many environments, but those that farmers construct in wetlands, as they did in pre-Columbian South America, are particularly large and extensive. Along with large complexes such as those shown in Fig. 5, there also occur small groups of raised fields that may correspond to exploitations of family-sized groups (Fig. 6). Denevan (2001) documents the geographic extent of raised fields and the diversity of forms observed throughout South America. In different parts of lowland South America, archaeological raised fields can be as long as 1,000 m or more

Farming Technology in Amazonia, Fig. 6 Small familial complex of pre-Columbian raised fields on the central coast of French Guiana (Photo by Stéphen Rostain)

(in Venezuela), as wide as 25 m (in the Llanos de Mojos of Bolivia), and as high as 2 m (Colombia). Little is known about the functional significance, if any, of this diversity, but some work in French Guiana suggests that fields may have been oriented so as to speed up drainage in

Farming Technology in Amazonia,

Fig. 7 Wooden shovel dated to 790 ± 30 years BP and found in a marsh near raised-field sites in Suriname (Drawing by Stéphen Rostain)

more flooded sites and retain moisture for longer periods in less flooded sites (McKey et al., 2010).

European chroniclers left scant anecdotal information on the tools that farmers used to construct raised fields and the methods by which they were managed (De Las Casas, 1560/1986; Gondard, 2008). Gumilla (1791/1963) described how Otomac Amerindians in the Venezuelan llanos built mounds using wooden shovels, and a remarkably well-preserved example of a wooden shovel was found in a marsh near raised-field sites in Suriname (Versteeg, 2003) (Fig. 7). There is archaeobotanical evidence (phytoliths) for cultivation of maize and of squash on raised fields in French Guiana (Iriarte et al., 2010). Microfossil remains of several other crop plants have been found in villages associated with raised-field farmers and were probably also grown on raised fields.

Like the creation and use of ADEs in forested environments, the construction and use of raised fields in seasonally flooded peri-Amazonian savannas has attracted considerable attention as an innovation that enabled indigenous Americans to overcome strong environmental constraints to agriculture (Renard et al., 2012). However, while the formation of ADE, and its use in farming, can still be observed in some parts of Amazonia (Schmidt, 2013), raised-field agriculture is virtually absent from South America today, having been abandoned centuries ago, subsequent to the European conquest, and in some cases much earlier. Attempts to understand how these wetland agricultural systems functioned have thus been virtually completely dependent on inferences from archaeological studies. These studies have

naturally tended to focus on what archaeologists can most easily see, i.e., the conspicuous vestiges of the raised fields themselves. However, focusing on these vestiges has likely given us an incomplete picture of technology and subsistence systems, because farming on raised fields was probably only one component of multi-activity subsistence systems. Raised-field agriculture may be understandable only when it is placed in a broader context of a more complex subsistence system. Bruno (2014) argues this point convincingly for wetland agriculture around Lake Titicaca in the Altiplano (Fig. 8), and it appears likely to hold as well for seasonally flooded savannas in the peri-Amazonian lowlands. In some cases, the importance of other subsistence activities is documented by archaeological evidence, such as the large complexes of earthen fish weirs identified by Erickson (2000) in seasonally flooded savannas of the Baurés region of Bolivia. Other activities, however, may have left no trace.

The limitations of archaeological studies have led to uncertainty and controversy about central aspects of raised-field agriculture, including how intensive and how productive it really was. Some have considered raised-field agriculture to be a way in which wetlands were used intensively but yet sustainably. By combining farming with the harvesting of aquatic resources and by recycling nutrients recovered from the flooded basin back to the cultivated fields, it is argued, raised-field farming supported dense human populations over long periods. Others, though, have questioned this conclusion. As Lombardo, Canal-Beeby, Fehr, and Veit (2011) argue, it is uncertain whether raised-field agriculture was really a

Farming Technology in Amazonia, Fig. 8 Flooded pre-Columbian raised fields near Lake Titicaca in the Peruvian Altiplano (Photo by Stéphen Rostain)

“pre-Columbian green revolution” or simply a “flood risk mitigation strategy.” For example, archaeologists have argued that the size of raised-field complexes indicates that they supported large human populations, but using the area of raised fields to estimate how many people they may have supported is an exercise fraught with uncertainty. Even if we accept measures of productivity of present-day experimentally created raised fields (summarized by Denevan (2001)) as indicative of the productivity of raised fields in the past, it is unknown what proportion of the fields in a region were cultivated at a given time. Were fields cultivated more or less continuously, or intermittently, with long-fallow periods? Did cultivation shift over the landscape with fluctuating water levels (Baveye, 2013)? Were fields used only a short time, being abandoned as new ones were opened? By itself, the impressively large area of raised-field complexes does not allow conclusions about how intensive or sustainable this kind of agriculture was.

Archaeologists have drawn on two other kinds of information in attempting to understand how raised-field agriculture in peri-Amazonian savannas may have functioned. First, a very old type of wetland agriculture, the *chinampas*, still persists – although considerably altered – in the valley of Mexico (Armillas, 1971). Archaeologists have sometimes assumed that findings on the *chinampas* can be generalized to other areas. However, the *chinampas* differ in many important ways from the peri-Amazonian systems (Renard et al., 2012). *Chinampa* agriculture is conducted in lakeshore environments and not in seasonally flooded savannas. Soils in the valley of Mexico are characterized by both alluvial and volcanic influences and are much richer than the acid soils of the peri-Amazonian savannas. Furthermore, in the mid-elevation climate of the valley of Mexico, crop pests and pathogens are much less of a problem than in the hot and humid Amazonian lowlands.

Secondly, archaeologists have gained insights from experiments designed to reconstruct or

Farming Technology in Amazonia, Fig. 9 Experimental modern raised fields near the Tiahuanaco site, Bolivia (Photo by Stéphen Rostain)

rehabilitate raised fields (Fig. 9). These experiments have been instructive, demonstrating, for example, the advantages conferred by the topographic heterogeneity that typifies raised-field systems in buffering variation in crop performance driven by inter-annual differences in rainfall (Erickson, 1992). By and large, however, the experiments have not been carried out over long enough periods to answer the most contentious questions, those concerning the necessity of fallow periods, and the sustainability of yield (Baveye, 2013). The experiments also have other important limitations. It is uncertain how well they replicate the ecological conditions and the plants of these environments in pre-Columbian times, as well as the technical practices employed in constructing and maintaining raised fields and the social organization that characterized pre-Columbian farmers. To the best of our knowledge, none of these experiments has resulted in long-term adoption of raised-field agriculture, but whether this can be ascribed to agroecological limitations (Baveye, 2013) or simply to factors that make raised-field

agriculture unadapted to today's social, cultural, or economic contexts (Erickson, 1994) is debatable.

Forty years ago, two pioneers of research on pre-Columbian raised-field agriculture in the Americas sought inspiration in a survey of contemporary raised-field agriculture in the Old World (Denevan & Turner, 1974). Until recently, however, few have followed their lead. New work on raised-field farmers of seasonally flooded savannas in the Congo Republic and in Zambia (McKey et al., 2014) shows the potential of research on these modern ethnographic analogies to suggest answers to contentious questions about pre-Columbian raised-field agriculture. For example, in the African systems studied so far – characterized, like peri-Amazonian seasonally flooded savannas, by acid and relatively infertile soils – the integration of fallow periods appears to be a constant. In the African systems, large quantities of biomass from adventitious plants and crop residues are incorporated into raised fields, and burning is often discouraged. This “slash-and-mulch” system appears to mirror

geoarchaeological evidence for limited use of fire during the period of raised-field cultivation in coastal savannas of French Guiana, where Iriarte et al. (2012) suggested that raised-field farmers employed a similar method of managing organic matter.

Conclusion

This article has discussed two examples showing how indigenous peoples of Amazonia devised farming systems that enabled them to adapt to severe environmental constraints. These and other farming systems that have stood the test of time (Mollard & Walter, 2008) may provide key insights in the search for ecologically sustainable agriculture (DeWalt, 1994; Koohafkan & Altieri, 2010; Martin, Roy, Diemont, & Ferguson, 2010; Renard et al., 2012). As in ingenious systems elsewhere in the non-Western world (Xie et al., 2011), we are just beginning to understand the ecological interactions underpinning their productivity and resilience. This article shows that indigenous farming technology in Amazonia continues to inspire research on agroecology in the past, the present, and the future.

Fengshui

Graham Parkes

Along with acupuncture, the best known representative of Chinese science in the West today is *fengshui*. The term is often translated as “geomancy,” though the two graphs that comprise the term simply mean “wind” and “water.” The practices associated with *fengshui* have been informed by ambiguity since their early beginnings – between a practice encouraging charlatanry based on mystification and a set of practical recommendations grounded in sensitivity to the natural environment. This article will ignore the mantic and divinatory aspects of *fengshui*, and the associated panoply of arcane symbolism of colors and animals and planets and stars, all of which distract from its more down-to-earth applications (For a more detailed treatment of *fengshui* is its broader context, see Parkes (2003) and see Geomancy in China in this Encyclopaedia).

It was not until the 1950s that Western scholars began serious investigation of Chinese sciences, as signaled by the first volumes of Joseph Needham’s monumental *Science and Civilization in China*. Needham devotes large sections of his second volume to the philosophies of nature found in Daoism and “the school of Naturalists” (the so-called *Yin-Yang* thinkers), the theory of the five elements (*wuxing*: better translated as “five phases of transformation”), symbolic correlations and correlative thinking, and the system of the *Yijing* (Book of Changes).

We have here for the first time a comprehensive, scholarly, and open-minded account of the philosophical and scientific background from which *fengshui* emerged. The practice of “geomancy” itself, however, Needham relegates to a chapter on “the Pseudo-Sciences,” considering it under the heading “Divination” along with such practices as scapulimancy (prediction of good or bad fortune on the basis of the behavior of ox and deer shoulder-blades when subjected to heat), astrology, chronomancy, cheiromancy, and the like. Operating on the straightforward definition of *fengshui* as “the art of adapting the residences of the living and the dead so as to cooperate and harmonize with the local currents of the cosmic breath [*qi/ch’i*],” he devotes four pages to a brief history and description of the practice (The quote is cited from the article by H. Chatley in Samuel Couling’s *Encyclopaedia Sinica* (1917)). After remarking on its advantages and drawbacks, he concludes that “all through, [*fengshui*] embodied a marked aesthetic component, which accounts for the great beauty of the siting of so many farms, houses and villages throughout China” (Needham, 1956: 2:361).

But if one considers the continuities between the basic features of the Chinese worldviews from which *fengshui* arose – the understanding of the world as a dynamic play of forces, or *qi* energies, rather than an aggregate of material things, with a corresponding emphasis on *becoming* over being, or *process* rather than substance – the scientific components of the practice will become as apparent as the aesthetic aspects.

The historical beginnings of *fengshui* are shrouded – appropriately for such an enigmatic science – in mystery. Marcel Granet cites as perhaps “the first mention of beliefs that are at the origin of geomancy” a passage in the *Book of Songs* (Shijing; ninth to fifth centuries BCE) where the founder of a town is said to have observed “the shadows” (which would indicated south) and also “the surrounding yin and yang.” Feuchtwang remarks in this connection that the application of *fengshui* principles to the layout of towns and cities is apparently much earlier than to houses and graves (Feuchtwang, 1974).

Another indication of an awareness of *fengshui* principles comes from a story concerning Meng Tian, the Qin Dynasty general who supervised the building of the first part of the Great Wall. Construction was begun in 221 BCE: “He . . . built a Great Wall, constructing its defiles and passes in accordance with the configurations of the terrain. It started at Lin-t’ao and extended to Liao-tung, reaching a distance of more than 10,000 li” (Cited from the *Shiji* (Records of the Historian), in the *Cambridge History of China* 1: 62). Thanks to its following the contours of the land, the Wall is traditionally seen as resembling a great dragon, which is an image that comes to refer in *fengshui* to any important topographical formation. Meng Tian is also credited with the invention of the camelhair writing brush, which eventually revolutionized the writing of Chinese characters. Thus in addition to being responsible for a good part of a 2,000-mile long “dragon” in the form of the Great Wall, he facilitated the production of countless smaller dragons – the image that characterizes calligraphy executed with especially vital energy – in the centuries since his death.

In 210 BCE, upon the death of his patron the first Qin Dynasty emperor, Meng fell victim to a dastardly political plot and was ordered to commit suicide. On hearing the news, he is said to have cried out in uncomprehending lamentation over this cruel stroke of fate. Then, on reflection, he said gravely: “I am guilty, and assuredly should die . . . A moated wall of more than 10,000 li; in the course of this work I cannot have avoided cutting through the earth’s veins [*di mo*]: this is my guilt.” He thereupon swallowed a lethal dose of poison (March, 1968, pp. 260–261). The *mo* of *di mo* (“earth’s veins”) corresponds to something in the human body like veins, or arteries, or pulses, but more closely to the acupuncture meridians, since no physical “envelope” for the flow is perceptible.

In a survey of the history of *fengshui* the Ming Dynasty author Wang Wei writes: “The theories of the geomancers have their sources in the ancient Yin-Yang school. Although the ancients in establishing their cities and erecting their buildings always selected the sites

(geomantically), the art of selecting burial sites originated with the *Burial Book* [Zangshu] in 20 parts, written by Guo Pu [276–324] of the Qin Dynasty” (cited in March, 1968, p. 261). Central to the *Zangshu*, also known as the *Book of Funerals*, is the idea that certain sites are blessed with flows of especially vitalizing energy known as *shengqi* (“vital breath,” “life energy”), which is a phase of the larger circulation of cosmic energies: “When the *qi* of yin and yang breathes out it is wind. When it ascends it constitutes the clouds, and when it falls it is rain. It travels on and in the ground and becomes vital *qi*. Vital *qi* travels on and in the ground and engenders the myriad things.” Vital *qi* is further subject to the forces of wind and water: “The [*Burial*] classic says that *qi* rides the wind and disperses. When bounded by water, it halts” (*Zangshu*, cited in Bennett, 1978, pp. 9–10). With respect to a place characterized by multiply dividing streams, the *Shuilongjing* (Water dragon classic) says: “If the wind shakes the willow branches, or if the wind bends the grass whether passing over the position or not, it will mean trouble, and even meandering water will not justify the site. It will bring decay and sickness” (Feuchtwang, 1974, p. 139).

Water molds the natural environs from the outside in obvious ways, primarily through watercourses’ cutting into the earth, but also through precipitation’s sculpting over time the shapes of mountains. Winds, too, move earth, if not mountains, over the long term – in ways less obvious than waters since the movement of air is itself invisible, becoming perceptible only through its effects on water, vegetation, and loose soil. But *fengshui* is concerned with winds and waters in a deeper sense too: with the invisible “breath of the earth” discussed above, and with the “flows” of *qi* beneath the earth that were thought to be responsible for the formation of minerals (Needham, 1970: 3:637, 650).

The art of proper burial consists in choosing a site with favorable life-breath. Guo Pu puts it succinctly by saying: *cheng shengqi*, “burying [is a matter of catching] life-breath” (cited in March, 1968, p. 256). The understanding of *qi*

expressed in the *Zangshu* has been aptly characterized as:

“the breath at the origin of things, forever circulating,” which flows through the whole of space, endlessly engendering all existing things, “deploying itself continuously in the great process of the coming-to-be and transformation of the world” and “filling every individual species through and through”. (Jullien, 1995, pp. 91–92)

The quality of a place, according to Guo Pu, depends on the local *shi*, meaning configurations of earth-energy (which François Jullien translates in this context as “lifelines”): “The vital breath circulates along the lifelines of the terrain and is concentrated at the points where they come to an end.” John Hay draws a helpful distinction between *shi* as “dynamic configuration” and *xing* as “form” or “shape” of concreted objects: “It is the changefulness of *shi* that is lasting, whilst the fixedness of *xing* is transient” (Hay, 1985, p. 53). On the *fengshui* understanding of a landscape, *shi* refers to both the “veins” of earth through which the *qi* flows and also the “skeletal structure” or “spinal column” of the terrain. In order to perceive the dynamic configurations of a landscape, it is necessary to gain some distance for a broader perspective: “The lifelines are visible from a thousand feet away, the particular configurations of the terrain from a distance of one hundred feet” (*Zangshu*, as cited in Jullien, 1995, p. 93). Another way, as Jullien suggests, is to consult an appropriate masterpiece of Chinese landscape painting, the primary principle for which was to “achieve the *shi*” of the landscape (99).

Another important source of ideas behind *fengshui* is the *Huangdi zhaijing* (The Yellow Emperor’s Siting Classic), attributed to the fifth-century thinker Wang Wei. As the title leads one to expect, a central idea in this text is that of *zhai*, meaning “site/siting” or “place/placing”: “All human dwellings are at sites. . . sites are the foundation of human existence” (cited in Bennett, 1978, p. 5). A *zhai* is therefore not merely some location in abstract space, but rather a place as defined both by a particular topography and by the kinds of human activities that take place in it (Western philosophy has generally devoted far

more thought to abstract space than to live place: for a judicious restoration of this imbalance, see Casey (1997)). Since an inhabited place is a dynamic locus of flowing energies, the *Siting Classic* addresses the temporal as well as the spatial aspects of *fengshui* practice: “Every year has twelve months, and each month has positions in time and space of vital and torpid *ch’i* [*shengqi* and *siqi*]” (Bennett, p. 7). Human activities undertaken at times of vital *qi* are more likely to be successful than at times when the *qi* is torpid. The quality of *qi* also varies within smaller cycles, such as the diurnal: Manfred Porkert characterizes *shengqi* as “the quality of energy during the *yang* hours of the rising sun (midnight to noon). . . [which has] a quickening and invigorating effect on active enterprises,” and the opposite for the *yin* hours from noon to midnight (Porkert, 1974, pp. 172–173). The *Siting Classic* also asserts an isomorphism between a *zhai* and a human body, a correlation that is central to Daoist thinking about the relations of the human being to the landscape: “The forms and configurations are considered to be the body; water and underground springs are the blood and veins; the earth is the skin; foliage is the hair; dwellings are the clothes; door and gate are the hat and belt” (Bennett, p. 13).

In spite of the prevalence of all these ideas, it was not until the Tang dynasty (618–906) that *fengshui* theories and practices began to be synthesized and formalized into a distinct school named as such (For example, the *Guanshi dili zhimeng* (Mr. Guan’s Geographical Indicator) attributed to the third-century author Guan Lo, the *Zhangshu* (Book of Funerals) attributed to Guo Pu, and Wang Wei’s *Huangdi zhaijing* (The Yellow Emperor’s Siting Classic); see Needham (1956, p. 360)). Wang Wei’s historical survey distinguishes two schools, one using the “Kiangsi [Jiangxi] method” and the other the “Ancestral Hall” or “Fukien [Fujian] method,” both of which he claims are derived from Guo Pu (March, 1968, p. 261). The latter (founded a century or two later) is also known as the “Compass School” and it emphasizes the importance of the Eight Trigrams of the Yijing and the Five Planets, as well as the

indispensability of the geomantic compass. Since this school's methods are more abstract and less scientific, it seems to have been infected by more charlatanry than its counterpart (A comprehensive account of the practices of the Fujian School, with fascinating descriptions of the geomancer's compass, is to be found in Feuchtwang (1974, pp. 18–95)).

The school employing the Jiangxi method is also known as the “Form and Configuration” (*xing shi*) School, because of its concern with intuiting the configurations (*shi*) of *qi* from the shapes or forms (*xing*) of the landscape. It was apparently founded by an imperial *fengshui* master by the name of Yang Yunsong (c. 840–888). In its consideration of mountains and watercourses the Form and Configuration School lays particular emphasis on the motif of the dragon as a pattern to be found in “all topographical formations” (Feuchtwang, 1974, p. 141), as indicated by the titles of such important treatises by the founder as the *Hanlongjing* (Classic on Arousing the Dragon) and the *Yilongjing* (Classic on Approximating the Dragon).

The dragon is best understood as an image for all vital topographical formations, since some places may simply be “dead” in terms of the flows of *qi*. As a later author, Shen Hao (seventeenth century), puts it:

Surely nothing but the writings of the magic dragon is an adequate figure of the mountain-ridges' permutations. What does not resemble the permutations of the magic dragon does not realize the subtle geomantic essence. Therefore it is said: if it has permutations, call it dragon; if it has none, call it barren mountain. (cited in March, 1968, pp. 256–257)

This is not the Azure Dragon as an image for one of the four directions, which is culturally and geographically specific to China, but “a universal symbol of the powers of nature” and especially of “the power of [self-]transformation.” (Feuchtwang (1974, pp. 149–150). See also the chapter entitled “The Dragon Motif” in Jullien (1995, pp. 151–161)). Since Chinese culture is based on the premise that all events in the world are continually transforming themselves, the

dragon is its perfect emblem. It is also an archetypal image common to a wide range of cultures and mythologies, in some of which its meaning is negative by contrast with its generally auspicious quality in China.

General Meng Tian's concern for respecting the earth is often echoed in the Ming period, which also saw a special flourishing of the art of garden making in China. Fear of damaging the “earth's veins” fueled opposition to gypsum mining in Taihe county in the fourteenth century, and the government prohibited the digging of ponds in ► [Nanjing](#) “lest they damage the *qi* of the earth in the imperial capital” (Clunas, 1996, p. 181). The sixteenth-century author of the *Nongshuo* (Talks on Farming) writes eloquently of “energy arteries running within the earth” and how “earth and bone are like the arterial system of the human body which carries the energy-blood” (cited in Hay, 1985, p. 42). When the body is understood as an organism situated within the larger organism of the environment, its various energetic pulses (*mo*) correspond to the dynamic configurations referred to earlier as the earth's “lifelines” (*shi*).

To fully appreciate sciences based on becoming rather than being, on energy rather than matter, we need to reorient our ways of perceiving our environment. In introducing his discussion of the notion of *shi* as “lifelines” in the earth, François Jullien recommends that we stop regarding nature as “an object of science” in the Western sense: “Rather, we should here perceive nature intuitively, through the sensibility of our bodies and their activity, as the single common principle within and outside us that operates throughout reality and explains how the world is animated and functions. Let us imagine a new ‘physics’ and stop thinking of nature abstractly” (Jullien, 1995, p. 91). If this idea seems too exotic – a physics associated with a transformation in our experience – we might recall that there exists something similar in the Western tradition, with the Hellenistic philosophies of the Stoics and Epicureans. As Pierre Hadot puts it: “Contemplation of the physical world and imagination of the infinite are important elements of Epicurean physics. Both can bring about a

complete change in our way of looking at things. The closed universe is infinitely dilated, and we derive from this spectacle a unique spiritual pleasure” (Hadot, 1995, pp. 87–88).

Just as the breath that animates the human body through bringing oxygen to the blood is invisible (the misty exhalations in cold weather being water vapor rather than air), so the cosmic breath animating the body of the earth cannot be seen, though it can be felt or otherwise sensed. The science of acupuncture, which is closely related to *fengshui*, has been slow to gain acceptance by practitioners of Western medicine. The main reason is that its background assumptions are so different, and there is also that fact that the meridians (*jingluo*) through which the currents of *qi* flow through the human body are invisible, and Western researchers were looking for literal conduits such as veins or nerves.

Corresponding difficulties arise with the idea of energies flowing through the earth (in the broad sense, including watercourses, vegetation, and the other processes of metal and fire) along “lifelines” that are invisible to the eye but can be intuitively discerned by the well-trained practitioner. This notion should, however, be less mysterious to Western physicists since the discovery of the earth’s magnetic field (the magnetosphere), whose energies flow along lines that are similarly invisible. Indeed the Chinese appear to have been the first to understand the phenomenon of magnetism, and texts referring to the “south-controlling spoon” – a piece of lodestone carved into the shape of the Northern Dipper (Ursa Major) – appear in China over a 1,000 years earlier than the first European references to the magnetic compass. These Chinese discoveries naturally took place within the context of *fengshui* (Needham, 1969: 71ff; 1962: 4/1, pp. 229–334).

In conclusion, a brief look at three Chinese arts will help further our understanding of *fengshui*, especially along the experiential dimension: landscape painting, garden making, and the martial arts and their derivatives.

We saw that Guo Pu understood the lifelines of the land as both its “skeletal structure” and its “veins,” and when the Form and Configuration

School of *fengshui* applied the image of the dragon to any important topographical formation, it was on the assumption that the dragon was animated by *qi* flowing through its bones as well as its veins. This idea is associated with the distinction between the “mountain” (*shan*) and “waters” (*shui*) *qi* animating a landscape (*shanshui*), with peaks and ridges as skeletal structure and watercourses as veins, and it is also exemplified in one of China’s greatest contributions to the world’s art, landscape painting (Feuchtwang, 1974, pp. 141–148). François Jullien quotes and comments upon the tenth-century aesthetician Jing Hao on this topic:

Under the painter’s brush, as in nature, “the aspects of mountains and waters are born from the interaction of vital breath and the given layout to which that force imparts dynamism.” In China, the purpose of painting is to rediscover the elemental and continuous course of the cosmic pulsation through the figurative representation of a landscape. (Jullien, 1995, p. 94)

Thus an excellent way of learning to discern the lifelines in a landscape is to study Chinese landscape paintings, which is in itself one of life’s great pleasures.

Another great Chinese contribution to the world of the arts, again associated with *fengshui*, is the art of the garden. We saw earlier that *fengshui* allows for certain kinds of human intervention in order to improve, when necessary, the conditions of a particular site – though the tragic figure of Meng Tian stands as a constant reminder of the dangers of too deep an intervention. As an important adjunct to the dwellings of the living in China – of the well-to-do in particular – the garden provides an opportunity to put the principles of *fengshui* into practice from the ground up, as it were.

The classic garden manual, the seventeenth-century *Yuanye* (Craft of Gardens) by Ji Cheng, talks of the way a well constructed garden, where one has “visualized the balustrades as if they were in a painting”, can “flood the heart with intoxication” and create “a pure atmosphere around our tables and seats [so that] the common dust of the world is far from our souls” (Ji, 1988, pp. 43–44). Chinese gardens would often be laid

out in such a way as to “borrow” features of the neighboring landscape, by offering views from within the garden of a local mountain or lake. A basic premise of the Chinese garden is the microcosm/macrocosm correlation between the human body and the physical environment: the well designed garden sets up a pattern of energies that corresponds to the dynamic configurations of a larger landscape – and indeed energies just as powerful thanks to the amplifying effect of miniaturization (The classic work on this topic is Stein (1990): see, especially, part one: “Trees, Stones, and Landscapes in Containers,” and “Survey of Themes.” For a brief history of the remarkable lithophilia (or petromania?) that has characterized the Chinese tradition, see Parkes (2005)).

For those of us unable to afford the luxury of a garden, there are other ways of cultivating an appreciation for the relations between the body’s energy configurations and those of the environment – through practices such as qigong (literally, “energy work”) and *taiji quan* (“Great Ultimate bare-hands-combat-technique”), one of the “softer” martial arts to have been developed in China. Anyone who is skeptical about the existence of the *qi* that flows through and energizes the body need only try some *qigong* exercises (for example, the set known as the “eight sections of brocade,” often used as a warm-up for *taiji* practice) in order to experience the flow of *qi* in his or her own person. As with yoga, the breath is central to *taiji* practice, insofar as breathing is a manifestation of the cosmic breath in the human body.

Taiji practice brings about precisely what *fengshui* encourages: a greater awareness of the relations between one’s activities and the configurations of the surroundings, whether natural or built. Unless one has the luxury of choosing a place to live and building a dwelling there, there is no opportunity for engaging in the practice of *fengshui* as “siting” and participating in the architect’s decisions concerning the orientation of the house in relation to prevailing sun, wind, rain, and terrain. But one can always change the ways one’s living space is configured in a residence already built, by the simple expedient of

becoming more aware of one’s activities in relation to the surroundings. It is quite possible thereby to improve the positioning of one’s furniture and personal effects without going to the expense of hiring an “expert” consultant. A little common sense combined with heightened sensitivity to one’s environment goes a long way. Opportunities to set up one’s workspace will generally be more limited than in the home, but improvement is usually possible nonetheless.

One might take encouragement from those writers on *fengshui* like Shen Hao who emphasize intuition. Coming upon a place that is right, he writes,

One’s eyes are opened; if one sits or lies, one’s heart is joyful. Here the breath gathers, and the essence collects. Light shines in the middle, and the magic goes out on all sides. Above or below, to right or left, it is not like this. . . . Try to understand! it is hard to describe. (cited in March, 1968, p. 259).

Among contemporary scholars, no one has put it better than François Jullien, who paraphrases Guo Pu as follows:

Not only my own being, as I experience it intuitively, but the entire landscape that surrounds me as well, is continuously flooded by subterranean circulating energy. . . . The most glorious sites will be those where it is most densely accumulated, where the circulation of the breath is most intense, its transformations most profound. . . . By rooting one’s dwelling here rather than elsewhere, one locks into the very vitality of the world, taps the energy of things more directly. (Jullien, 1995, p. 92)

If in response to such an expression of the more sensible tenets of *fengshui* we could become skeptical concerning the modern conceit that we can be at home anywhere, no matter where, and instead practice some environmental science at the personal level, we would surely witness a greater flourishing on the part of human beings and the natural environment on which we depend.

Fertility in Historical China

Zhongwei Zhao

The Australian National University, Canberra, Australia

According to available records, the population living in areas controlled by China's Western Han dynasty (206 BC–25 AD) was already

close to 60 million in the year 2 AD. In the next thousand years, China's population size varied greatly between 20 and 60 million, and its reduction was often related to wars, famines, pandemics, natural disasters, and the decrease in the territory administrated by the imperial government. Noticeable population growth took place in the eleventh and twelfth centuries when the Chinese population was very likely to have reached 100 million. This was followed by further fluctuations in its number in the next few centuries. By the early seventeenth century, the Chinese population increased to 100–150 million. It rose further to about 440 million in 1850 (Ho, 1959; Zhao & Xie, 1988) and 550 million in 1950 (Yao & Yin, 1994). For most of the last two millennia, the Chinese had about a quarter of the world's population.

Partly due to its large population size, four interrelated beliefs or viewpoints about China's past fertility level and reproductive behavior existed widely, and they are still held by some researchers and ordinary people today. These beliefs and viewpoints can be summarized as follows: First, “the fecundity of the Chinese was without parallel” and their “birth rate was abnormally high” in the past (Mallory, 1926). Second, this high fertility resulted because the Chinese did not control their family size. Even if the fertility level in some historical populations was only moderate, its reason “was not deliberate fertility control” (Wolf, 1985; Wolf & Engelen, 2008). Third, the Chinese did not control their fertility, because they had a very pronatalist culture. The Chinese not only liked to have children; they liked to have “as many children as possible, preferably sons” (Chandrasekhar, 1967; Hassan, 1980). “Far from limiting the number of sons reared, Chinese families made every effort to maximize the number” (Wolf, 2001). Fourth, anti-natalist ideas were rarely discussed among Chinese intellectuals in the past. “When Chinese officials worried about the balance of population and resources, they did not advocate birth control as the solution” (Wolf, 2001).

Recent demographic investigations have found however that fertility patterns and people's reproductive behaviors in historical China were

far more complex than those portrayed by the above oversimplified views. The above claims do not accurately represent China's historical reality.

Research findings revealed that in comparison with that recorded in the Hutterites and many preindustrial European populations, marital fertility in historical China was not high but only moderate (Coale, 1985). In some historical European populations, total marital fertility rates were often between 8 and 10 children, but they usually varied between 5 and 7 children in most historical Chinese populations studied up to date. This difference arose largely because compared with their European counterparts, Chinese women married relatively young, but they often took a longer time to have their first child. Chinese women also had longer intervals between successive births and stopped their reproduction at younger ages (Lee & Wang, 1999; Zhao, 1997a).

The relatively low fertility observed in many historical Chinese populations was related to many factors. The practice of child marriage, which existed in many parts of China, tended to go against the natural inclination between spouses, because childhood association could lead to an aversion between them and consequently caused a decrease in the incidence of marital sexual relations (Wolf & Huang, 1980). The intensive and prolonged breastfeeding could lengthen the period of postpartum amenorrhea and delay the next pregnancy (Liu, 1992). The comparatively low coital frequency found in some Chinese populations directly influenced the chance of conception (Barclay et al., 1976; Lavelly, 2007). Low standards of living and poor health could also lower the rate of conception and increase the incidence of spontaneous abortion. Furthermore, the moderate fertility level could be related to periodic separation between spouses caused by seasonal migration (Coale, 1985).

In addition to the factors listed above, recent studies have found that people's reproductive behavior was closely related to the sex composition of children they already had and their children's survivorship. In comparison with those who already had both sons and daughters, couples who had only daughters or sons were more likely

to have another child. Their birth interval to that child was generally shorter, and their mean age at last birth tended to be higher. In comparison with those whose first few children all survived, women whose first few children all died were more likely to have stopped childbearing at older ages (Zhao, 1997b). These patterns were observed in normal times and in periods of hardship. During China's 1958–1961 famine, for example, fertility fell far greater among women who already had a larger number of surviving children, especially those who already had both sons and daughters in comparison with women who had a smaller number of surviving children, especially those who did not have sons (Zhao & Reimondos, 2012). Recent studies also revealed that in the past people's reproductive behavior and fertility level were notably affected by the social status of their family, their position in the family, and the composition of their household (Wang, Campbell, & Lee, 2010). These new research findings show that in Chinese history, a considerable number of people might not want to have as many children as possible, but rather considered their reproduction carefully and deliberately controlled their family size.

In addition to the revealing demographic patterns summarized above, recent studies have uncovered a considerable amount of surviving written evidence that recorded people's consideration about their ideal family size and why did they want to control it in the past (Zhao, 2006). For example, *Sheng Zi Bu Ju* or infanticide existed in many areas of China in Song dynasty (960–1279AD), which was recorded by many scholars and officials (Zang, 1995). In discussing this phenomenon, several well-known historical figures noted that "peasants usually wanted to have two sons and one daughter. If more were born, they would be killed" (Su, eleventh century). "People wanted to have only two sons. They drowned all the rest thereafter regardless of their sex" (Zhu, twelfth century). "People kept only one or two children or sons, and the rest would be killed by drowning" (Li, twelfth century). These records unveiled a fact that many people did not want to maximize their family size or the number of sons. In commenting on

the cause of such behaviors, it was noted that “people had children according to their economic ability. Even the gentry behaved accordingly. . . . Rich families had no more than two sons and one daughter. Middle and lower class families generally had only one son” (Yang, around the end of eleventh century). People controlled their family size, because they wanted *Ji Chan Yu Zi* (Yang, around the end of eleventh century) or *Ji Chan Shou Kou* (Fan, around the end of eleventh century), which literally mean having children according to their ability and wealth.

Strictly speaking, the above records should not be regarded as evidence of intentional birth control, because what had been controlled was the number of surviving children. The intention of citing these examples surely is not to suggest that infanticide is the same as the control of fertility, but rather to show that as early as about a thousand years ago a considerable number of people wanted to limit their family size and their decisions stemmed directly from the consideration of their long-term economic interests.

The intellectual discussion of population issues in historical China was also more complicated than that assumed by some researchers. Anti-natalist ideas were discussed among intellectuals in Chinese history. Some of their writings are still available. As early as more than 2,000 years ago, the impact of rapid population growth on the society was already noted by Han Feizi (c. 280–233BC). Such concern was also expressed by other scholars in the next two millennia and showed a notable increase in recent centuries. This increase seemed to have been related to the rapid population growth taking place over this period. In addressing these issues, ideas relating to population growth rate, population doubling time, stationary population, negative effects of having a large population, and the relationship between population growth and natural resources were discussed by a number of scholars. It is particularly noteworthy that Hong Liang Ji (1746–1809AD), an official and scholar, believed that the speed of population growth in the early Qing period had overtaken the growth of means of subsistence. Hong’s ideas and theory

were all very similar to, but developed a few years earlier than, those proposed by Malthus. Because of that, Hong has been widely regarded as the “Chinese Malthus” (Silberman, 1960). Another Qing official and scholar, Wang Shi Duo (1814–1889AD), held more extreme views on population growth. He believed that rapid population growth had led to land being over-cultivated and becoming no longer able to provide adequate subsistence for the people. This led to poverty and social upheaval. According to him, the population had to be reduced by 70 or 80 % in order to solve these problems. On the basis of these judgments, he proposed a whole set of measures, including some extreme, cruel, and inhuman ones, to control the population growth (Zhang & Yang, 1988). People may have different views about these ideas and suggestions, but they have shown that anti-natalist ideas were discussed by Chinese scholars. They understood that population increase and fertility could be controlled through postponing marriage, lowering the proportion marrying, preventing women from getting pregnant, limiting the number of births, and wide use of contraception and abortion. When they worried about the increasing population pressure, they advocated these measures as solutions for China’s population problems.

The Chinese population entered a period of very rapid growth in the mid-twentieth century, because of its remarkable mortality decline and relatively high fertility. By 1970, China’s national population already reached 830 million (Yao & Yin, 1994). This put a great pressure on the country’s economic development. Facing this challenge, the Chinese government started its nationwide family planning program. Like many countries in the world, China has witnessed a great reduction in fertility since the early 1970s. Its total fertility rate fell to below replacement in the early 1990s and then to far below replacement around the beginning of the twenty-first century. Thanks to these changes, the growth of the Chinese population has slowed down significantly. China will lose its title of world’s most populous country to India and start a long-term population decline in one or two decades.

Fishing in Ancient Egypt

Dietrich Sahrhage

Early civilization in the Nile valley developed mainly because of heavy summer rains in the highlands of Ethiopia and around the East

Fishing in Ancient Egypt,

African lakes. Every year a huge flood reached Egypt around mid July, carrying to the lower parts of the Nile enormous quantities of fertile silt. This settled as soil especially suitable for agriculture and filled up the Delta, originally a bay of the Mediterranean Sea. The timing and intensity of the floods determined whether people would have wealth or famine, depending on the water supply and agricultural production.

The waters of the Nile, the floodplains, and many pools that remained when water receded or evaporated in autumn, as well as the coastal lagoons of the Delta, contained rich resources of fishes and other aquatic animals which were utilized since prehistoric times. There is much evidence for this from archaeological finds, well preserved in the desert, engravings and wall paintings in tombs and temples, and from hieroglyphic inscriptions.

As indicated by bone and shell remains at Kom Ombo near Aswan, hunter-gatherers already fished during the Late Palaeolithic around 15000 BCE for Nile perch, catfishes and barbels, and they collected Nile oysters and African

softshell turtles. Some flint tools have been interpreted as points of lances. After 10000 BCE, as North African savannas deteriorated to deserts due to climatic changes, game became rare, and hunters turned increasingly to fishing, employing gear like spears with stone or bone points, harpoons, and curved fishhooks and gorges made of bone or antlers (Figs. 1 and 2). Hippopotamuses and crocodiles were also harpooned or caught in traps (Fig. 3). The development intensified during the Neolithic (5500–4000 BCE), when Lake Quarun in the Faiyum Depression filled with water and became an important fishing area like the Delta. Around 3500 BCE the first fishhooks of copper appeared and increasingly replaced the stone and bone tools.

The unification of Upper and Lower Egypt around 3000 BCE led to the formation of the Old Kingdom (ca. 2600–2150 BCE) with powerful rulers and an efficient administration, promoting the construction of pyramids and hydraulic engineering for drainage and irrigation to improve agriculture, fishing and

clipped mullet and its roe hanged for drying (Épron & Daumas, 1939; Keimer, 1939; Moussa & Altenmüller, 1977; Petrie, 1892; Taylor & Griffith, 1894; Wreszinski, 1914)

transport. During this epoch artists created very realistic images of fish species and fishing methods in reliefs and wall paintings on tombs, mainly at Saqqara, the necropolis of Memphis (*Mennofer*), the old capital (Fig. 4). The fishes frequently depicted are Nile perch, Nile tilapia, various species of catfishes and elephantfishes, barbels, mullets and eels (Fig. 5). Modern studies revealed about 65 fish species in the Nile waters; some 30 of them can be recognized in ancient images. Presentations of fish and fishing had revivals during the Middle and New Kingdoms (ca. 2000–1780 and 1550–1070 BCE), particularly at Thebes, west of Luxor, and elsewhere. A considerable number of marine species from the Red Sea/Indian Ocean are depicted under ships of the expedition to Punt in reliefs of the mortuary temple of Queen Hatshepsut at Deir el-Bahri.

Famous pictures in tombs show the deceased spearing fish, usually Nile perch and tilapia, in

the papyrus swamps (Fig. 6). Many images illustrate the use of weir baskets (Fig. 7) and of nets, mostly small hand nets and seines, operated both from the beach and from boats (Figs. 8 and 9). Fishermen made and repaired seine nets of flax or other natural fibres (Fig. 10) which were kept vertical in water by floats and sinkers. Trawls pulled between two boats may even have been used (Fig. 11). Cast nets appear in the Late Period. Fishing vessels were papyrus rafts and boats constructed from blocks of wood, since large trunks were scarce (Fig. 12).

As shown in wall pictures, fishes, mainly Nile tilapia, were kept in basins, apparently mostly waters belonging to palaces or temples. A few presentations seem to indicate that fish were also kept in natural ponds, perhaps as storage of living food (Fig. 13).

Fish were gutted and eaten raw or grilled. Large quantities were clipped and dried in the

sun, often hanging on lines. Salted fish also had a wide market both in Egypt and for export (Fig. 14). Some sort of caviar was prepared from mullet roe. It seems that fish for food consisted almost exclusively of freshwater species.

The profession of fishermen was regarded socially as only of a low level. Various images show how they participated in coarse games, knocking each other from the boats with long poles.

Catches usually had to be delivered to palaces or lords of the manor, and fish were often used, jointly with other natural products, as payment in kind for labour. Catches were subject to taxation, and fees had to be paid for fishing rights.

Also well documented is the important role of fishes and other aquatic animals in religion, mythology and medicine. In many provinces different fish species were adored as representing gods, e.g. African butter catfish (*Schilbe mystus*) as a symbol of Hatmehit at Mendes in the Delta, Nile tilapia as a symbol of fertility and rebirth, elephantfish as a symbol of Hathor at Oxyrhynchus and other places, *Lepidotus* (*Barbus bynni*) at Lepidopolis near Abydos, Phagros (mullet?) and puffer fish at Aswan, and Latos (*Lates niloticus*) at Esna. Devotion to fish was often combined with a ban on the consumption of certain fish species at certain times in certain areas, especially by priests in temples. Mainly during the New Kingdom and Late Period thousands of fishes were mummified and buried in large animal cemeteries. Fishes were found as gifts to the deceased in graves, and fish offerings were portrayed on tomb walls, although infrequently.

As described in papyri, extracts from various parts of fish were used as drugs for medical purposes. For curing gout, live electric catfish (*Malapterurus electricus*) were placed under the feet of patients.

Fishing in Mesopotamia

Dietrich Sahrhage

In Mesopotamia, the region of the rivers Euphrates and Tigris and their tributaries, the formation of old civilizations depended on water for drinking, agriculture, traffic and trade. Living aquatic resources like fish, crustacea, molluscs and turtles contributed substantially to feeding the growing human population.

Fishing in Mesopotamia,

Fig. 1 Fishing with hook and line on the river banks. Drawing after a relief in the Southwest Palace of King Ashurnasirpal II (883–859 BCE) at Nimrud (Layard, 1853)

Annual floods, originating from rainfall and meltwater in the highlands of Anatolia and the Zagros Mountains, transported large amounts of pebble and fertile silt downstream; rivers frequently changed their channels, often with catastrophic consequences. During highest water-levels (April–June) wide areas were flooded until water ran off or evaporated in the hot climate. Swamps with reed thickets and lakes (Hors) developed in the depressions. Floods became less dangerous when rivers were regulated with dams and canals, and when irrigation was implemented in the south, from at least 5000 BCE. The many waters were productive areas for fishing.

Investigations have shown that Neanderthals lived in northern Mesopotamia as nomads at least 100,000 years ago. During the Neolithic, after 10,000 BCE, the people formed settlements and developed farming and animal husbandry. The oldest evidence for fishing activities are points

Fishing in Mesopotamia, Fig. 5 Pride of the fisherman: A large barbel (*Barbus esocinus*), probably the prototype of the Apkallu (Photo: H. Pfälzner. Used with his permission)

of spears and arrows of flint and obsidian, fish bones and shells of river mussels (*Unio tigridis*) from around 5500 BCE.

Reports on clay tablets seem to indicate that fish-hedges, traps and baskets were widely used; however any evidence we have has decayed long ago. Fishhooks of stone have only occasionally been discovered, but hooks became more numerous after the implementation of tools of copper around 4500 BCE and bronze (copper-tin alloy) around 3000 BCE. Hook and line fishing is represented in many reliefs (Figs. 1 and 2). According to texts in cuneiform

Fishing in Mesopotamia, Fig. 6 Clay tablet from Lagash with text in cuneiform script listing the quantities of various fish species delivered by the fisherman Lugal-sala-tuku to the palace of King Urukagina, ca. 2350 BCE (Staatliche Museen zu Berlin-Preussischer Kulturbesitz, Vorderasiatisches Museum) (Used with their permission)

characters, net fishing was frequently used. Stationary nets were set between stakes and seine nets used from the beach, probably also from reed rafts and boats, to encircle fish shoals (Fig. 3). Cast nets were also known. Impressions of cylinder seals often show fishing activities (Fig. 4).

Mesopotamian graves are much simpler than Egyptian tombs, where fish images, particularly from the Old Kingdom, are presented naturalistically. In contrast, Mesopotamian reliefs, sculptures and cylinder seals show such pictures, but they are fairly stylized. However, rich finds of ancient fish bones from food remains on many sites provide the possibility of identifying a great number of fish species by comparing them with skeletons of modern fishes. Such investigations revealed that various species of barbels, some of very large size (Fig. 5), catfishes and mullets formed the bulk of catches in freshwater areas, whereas sea breams, grunts, croakers, groupers, and many other marine fishes were caught along the

Fishing in Mesopotamia, Fig. 7 Investiture of King Zimri-Lim (1782–1759 BCE). Colored wallpainting from the palace at Mari, central panel. In the lower part streams of water and fishes can be seen (Parrot, 1958)

F

Fishing in Mesopotamia, Fig. 8 Detail of impression from cylinder seal: God Enki (Ea) with running water and fishes. Akkadic period, ca. 2360–2180 BCE. Height 3.8 cm

coasts of the Arabian/Persian Gulf. Frequent finds of marine fish remains far inland prove that these animals were traded over long distances. The same holds true for marine mussels and gastropods, which were converted into ornaments, inlaid work and objects of daily life.

Texts on thousands of clay tablets with writing in cuneiform characters permit a deep insight into many aspects of Mesopotamian matters, especially in the fields of economics, legal affairs, medicine, religion and literature. From these scripts it can be seen what names in Sumerian and Akkadic languages people used for various species of fish. Most of the 324 names collected could not be attached to a certain fish species, but some could, like *kusu* for the dangerous Ganges shark (*Glyphis gangeticus*) which migrates upstream from the Gulf to the north of Baghdad.

The texts also provide information on the organization of fishing, commitments and wages of fishermen, as well as facilities for

Fishing in Mesopotamia, Fig. 9 Mixed figures in Mesopotamian mythology: (a–c) Goat-fish; (d) Dragon and birdlike beings with fish tail; (e) Fish-man and fish-

woman; (f, g) Apkallu (After Legrain, 1936; Potraz, 1961; Scheil, 1918; Thureau-Dangin & Durand, 1936)

Fishing in Mesopotamia, Fig. 10 Fish-man on quare stone from Tell Halaf, Syria, ca. 900 BCE. Limestone, ca. 40 × 60 cm (Staatliche Museen zu Berlin-Preussischer Kulturbesitz, Vorderasiatisches Museum) (Used with their permission)

the delivery and distribution of catches. Regulations were most rigid around 2300–1600 BCE, when palaces and temples played a central role for the public production, storage and distribution of foodstuffs and commodities. Detailed statistics were collected regarding the deliveries of fish (Fig. 6). Sometimes temples let out fishing rights to independent fishermen who paid a fee in the form of fish and delivered the rest to trade agents who organized the barter on the basis of silver equivalents for natural goods.

In the vicinity of rivers, lakes and the Gulf, fish were mainly consumed fresh. Because of the hot climate and because fish are perishable, large parts of the catches had to be processed. The fish were gutted, and the marine fish were mostly clipped, dried in the sun, crushed and pressed to blocks suitable for transport over long distances. Freshwater fishes were dried for longer times in the shade. Salting seems to have been less important, but many fish were put into brine prepared from fish guts

Fishing in Mesopotamia, Fig. 11 Impressions from cylinder seals with mythological scenes related to fishing (After Amiet, 1972/1980; Orthmann, 1975; Weber, 1920)

and crustacea, possibly a forerunner of garum in Greek and Roman times.

Texts on clay tablets also describe medical prescriptions against various diseases in which substances from fish, turtles and seaweeds were considered helpful. Doctors and priests collaborated closely during magic exorcism.

Fish were an important element in Mesopotamian religion and mythology. From the many gods of the Mesopotamian pantheon it was particularly Enki (Ea in Akkadic), the creator of man and god of wisdom, who was adored as the donor of water and fertility. Usually he was depicted carrying a vase

through which water from heaven flowed down to earth (Figs. 7 and 8), while fishes, as symbols of life and fertility, swam upwards in the running water. Enki's attributes were goat-fish and fish-man (Figs. 9 and 10). Frequent figures related to Enki are also men, dressed in the skin of a large fish, probably a barbel (*Barbus esocinus*) (Fig. 5). These figures (priests?) presented in cylinder seals, sculptures and many reliefs, are called Apkallu, which means sage. A great number of cylinder seals show scenes with fishing, boats, fish offering and libation ceremonies (Figs. 11 and 12).

Fishing in Mesopotamia, Fig. 12 Impressions from cylinder seals with scenes of fish offerings and libation ceremonies (After Amiet, 1972/1980; Buchanan, 1966; Heuzey, 1936; Perrot & Chipiez, 1884; Weber, 1920)

Fishing in the Indus Valley

Dietrich Sahrhage

The ancient civilization in the region of the Indus valley reached its zenith around 2600–1900 BCE. It was characterized by cities like Harappa, Mohenjodaro, and many urban sites which have been excavated or identified by archaeologists in what is now Pakistan and Western India.

It was the regular supply of water that allowed the early development of agriculture and hence the growth of the human population. The main sources were the rainfalls and melting snow from the Hindukush and Karakoram Mountains in the north and monsoon rains from the west. This resulted annually in mighty, though very

Fishing in the Indus Valley, Fig. 1 Steatite stamp seal from Mohenjodaro with pictogram of fish in the script line on top, 3.5 × 3.5 cm. National Museum Delhi (From Jansen, 1986, drawing Bunse, Aachen. Used with their permission)

variable, floods in the River Indus and its effluents with a peak in July and August. The water carried enormous quantities of very fertile soil to the south, which filled the riverbeds and forced streams to change their channels frequently, inundating large areas.

The rivers, numberless lakes and pools, often arising and vanishing, and the waters of the Arabian Sea along the Makran coast were the home for large resources of fish, crustaceans and molluscs. These animals formed a significant element in the diet of people and of the trade in the region.

Since the Indus script and language have not yet been deciphered, and there seem to be no reliefs or wall paintings in temples or palaces, we depend mainly on archaeological finds and on the observation of apparently old practices today for information on fishing and other activities in ancient times.

The importance of fishes in the Indus civilization is evident in many typical seals with a pictogram of fish (Fig. 1). Presentations of fish and fishing also appear on pottery and in the form of small zoomorph ceramic figurines (Fig. 2). Most interesting is a potsherd, discovered at Harappa,

Fishing in the Indus Valley, Fig. 2

Fish images on pottery and in figurines: (a) Red/black ceramic vessel from prehistoric cemetery at Nal (Baluchistan) (Used with their permission), (b) painted dish on stand with fish from Lewan, ca. 3000 BCE (Allchin, 1982/1993), (c) zoomorph figurines with fish design

Fishing in the Indus Valley, Fig. 3

Potsherd from Harappa with painted men fishing with baskets, in front probably seine net (After Vats, 1940 from Jansen, 1986. Used with their permission)

with the drawing of men obviously fishing with baskets (Fig. 3). In the foreground one sees netting which could be interpreted as part of a seine. The existence of such nets is revealed by a great number of typical sinkers, mostly of limestone. Pakistani fishermen still use the same type today. Direct evidence for net fishing is provided by remains of an almost 5,000 year old net discovered in 1972 by an Italian mission at Shahr-i-Sokhta in the Seistan Depression, today in Iran near the border with Afghanistan (Fig. 4).

Finds of ancient fishing gear consisted mostly of spear points, arrowheads and a limited number of fishhooks (Fig. 5). Spears and arrows were certainly also used for hunting. With the development of metallurgy since the fifth millennium BCE, artefacts were made of copper. Fishhooks discovered at Mohenjodaro, Chanhudaro and Harappa were 1–10 cm long. The longest must have been employed in fishing for very large fishes. Hooks were mostly barbed, but barbless hooks were also found. From investigations it

Netting knitted with reef knots, square mesh 4 cm on average, finely woven fibre, possibly wool (Istituto Italiano per l'Africa e l'Oriente, Rome. Photo: Bonardi. Used with their permission)

F

Fishing in the Indus Valley, Fig. 5

Fishing gear in the Indus civilization: (a) Copper fishhooks from Mohenjodaro (Sarkar, 1953); (b) spearpoints and arrowheads (Agrawala & Kumar, 1993); (c) net sinker of limestone discovered at Mohenjodaro (Marshall, 1931/1973)

appears that copper was imported from Baluchistan, Rajasthan (Khetri) and overseas from Muscat and Oman (Magan).

In the absence of ancient fish images, skeletal remains are of utmost importance for identifying fish species caught in ancient times. From fish bones unearthed in Mohenjodaro, Harappa and elsewhere it is indicated that catches in freshwaters consisted mainly of carp-like fishes, particularly the large barbels *Catla catla*, Mahseer (*Tor tor*) and the Rohu (*Labeo rohita*), which grow to lengths of over 2 m, and also various species of small barbels which nevertheless are important

due to their biomass. Also the large catfish *Wallago attu* was a major food fish.

The coastal waters of the Arabian Sea provided good catches mostly of giant seacatfishes (*Arius thalassinus*), croakers, grunts, skates and small sharks. This was discovered when a French team with Desse and Desse-Berset in 1989 found thousands of fish bones, together with shells and Harappan potsherds, lying on the Prahag beach near Pasni. Finds of such bones at Miri Qalat, 120 km north of Prahag, and even at Harappa, some 900 km further north, prove that fish had been transported far inland.

Fishing in the Indus Valley, Fig. 6 Reconstruction of the city of Lothal with harbour basin, wharf and store. Large central building ("acropolis") on platform of loam

bricks. In the back living quarters and workshops for copper, marine shells, lapidary and semi-precious stone working industries (Rao, 1973)

In a region with a hot climate this would have been impossible without proper conservation of the catches near the coast. The bone remains on the beach of Prahag gave a hint: they were placed in a number of circles 5–8 m in diameter. It seems that the fishes had been put into round pitches in the sand for salting. In fact, this method is being used by present-day Baluchi fishermen, as Belcher observed at Balakot near Karachi. The fish, mostly silver grunt (*Pomadasyss hasta*), are beheaded, clipped, the halves put into brine for 2–3 days and exposed to wind and sun for drying.

Rivers, lakes, and the Indian Ocean offered good opportunities to catch crustaceans and to collect mussels and gastropods. Whereas the crustaceans remains decayed, the mollusc shells lasted over thousands of years. Already during the Stone Age they were worked into ornaments, amulets and objects of daily life like vessels and spoons. Workshops existed in many Harappan

cities, where craftsmen produced highly artistic objects with fairly uniform techniques and styles. Like precious stone products, mollusc shell products were also traded in the Indus region and far beyond (Kenoyer, 1984).

The central part (columella) of sacred conch (*Turbinella pyrum*) was used to produce hollow cylinders for seals which were exported to Oman and Mesopotamia. Finds of such cylinders, and of Indus stamp seals, in Mesopotamia prove trade connections between Meluhha (as the Indus region was named) and the cities on the rivers Euphrates and Tigris. Cuneiform scripts on clay tablets from Mesopotamia tell that King Sargon I, around 2300 BCE, ordered that ships from Meluhha sail upstream on the Euphrates beyond Ur to reach his capital Akkad for unloading their cargo. After the Akkad period direct connections were discontinued but indirect links via Dilmun on the Bahrain Islands and Oman lasted for many years.

One of the ports for trade overseas was Lothal on the Bay of Cambay, where a basin and likely harbour installations and workshops have been excavated (Fig. 6).

The Indus civilization perished around 1700 BCE for unknown reasons. Possible explanations include climatic changes, tectonic activities with earthquakes, and socio-economic influences like overgrazing, burning of grassland and forests, and the impossibility for rural people to feed the increasing urban population.

Fishing in the Stone Age

Dietrich Sahrhage

Fishing is one of the oldest activities of man. The hunter-gatherers of the Stone Age not only fed on game and plants but also on fish and other aquatic animals. Living as nomads, they were bound to the neighbourhood of springs, rivers and lakes for drinking water, hunting game at the watering places and using the dense vegetation. No wonder that they soon discovered rich aquatic resources for their food. Also in coastal areas, preferred as migratory routes, they were able to collect and catch many fishes, crustacea and molluscs.

It is striking that fishing gear was developed in different regions of the world to rather similar, sometimes almost identical, forms, although the globe was still only thinly populated. Whether the various techniques were invented independently in different civilizations since human intelligence led to similar solutions (convergence), or whether the experience was distributed by migrations and cultural exchange (diffusion), is an open question.

The oldest indications of fishing, about 2 million years old, are bones of Tilapia and shells of molluscs together with simple pebble tools and human bones left by *Homo habilis* in the Olduvai Gorge in Tanzania, but no fishing gear was found.

It may, however, be assumed that already during the Palaeolithic times humans were able to

Fishing in the Stone Age, Fig. 2 Harpoon of prehistoric fishermen on the coast of southern Peru used for hunting seals and possibly sharks. The harpoon consists of seal bone with a flint point and ligature of leather or

sinew. Shaft is of wood, retrieving line of plant fibre (Lavallée, *Pour La Science* 2001. Used with the permission of *Pour La Science*)

Fishing in the Stone Age, Fig. 3 Atlatl, spear throwing sling from the cave of Mas-d'Azil, Ariège, southern France, about 20,000 years old (After Stodiek & Paulsen, 1996). The 32 cm long stick is decorated at the end with a

highly artistic sculpture of a fawn and a bird. The end of a spear is put against a spur of the sling, and – as with a catapult – the hunter can propel the spear with a force much greater than that of a hand-thrown spear

develop a palette of simple techniques to reach their goal. Men went hunting for fish with the same gear used for small game, particularly with wooden lances equipped with stone points

(Fig. 1). Women and children collected crustacea and molluscs in shallow waters. People soon managed to catch fish with their bare hands and to build stone walls and wooden hedges to

Fishing in the Stone Age,

Fig. 4 The gorge, probably the oldest angling tackle. In Europe it has been used since the Magdalenian, about 16,000 years ago. The stick is put into the bait. When the prey snaps at the bait, the gorge turns transverse as the line gets tight (Evers, 1988. Used with their kind permission)

Used with the permission of *Pour La Science*)

improve fishing possibilities. Branches of bushes were stuck into the ground in waters where fishes concentrated to shelter. The hunters also discovered that fish were attracted by light from fire. Most likely they built fish traps similar to those used for game, but any material evidence decayed long ago.

A great step was the invention of the javelin. This tackle was used by *Homo erectus* some 400,000 years ago, as proved by finds in Lower Saxonia, Germany.

Neanderthals (*Homo sapiens neanderthalensis*), living in Europe and the Near East some 200–30,000 years ago, fed mainly on meat, as indicated by their petrified excrements, but fish also played an important role. This was shown by bone remains of trout and salmon on their resting places along rivers in France and Spain.

Much progress was achieved after modern man (*Homo sapiens sapiens*) originated. This began about 150,000 years ago somewhere in southeastern Africa and spread out over the globe, reaching Australia around 40,000 BCE and the American continents via the Bering Straits about 15,000 BCE, perhaps earlier. Now more delicate spear points, blades and scrapers of stone, were produced, and later tools of bone and antler.

Fishing in the Stone Age, Fig. 6 Reconstruction of a fish hedge with trap from Oleslyst, Denmark, about 4,500 years old. Hazel stakes in the sea bottom held wickerwork panels over a length of about 45 m. Fish,

mostly eels, swam along the hedge to deeper water and were caught in a weir at the end (Pedersen, 1997; drawing Petersen, Kalundborg Regional Museum. Used with their permission)

F

Fishing in the Stone Age,

Fig. 10 Barramundi fish (*Lates calcarifer*) painted by Australian aborigines about 2–3,000 years ago in “Roentgen” (X-ray) style in the Cockatoo National Park, western Arnhemland (Photo: Tacon, The Australian Museum, Sydney. Used with their kind permission)

Modern humans invented the harpoon, a sharp barbed piece of bone, detachable from the spear shaft, which kept the prey (game or fish) on a retrieving line when it stuck in the body of the animal (Fig. 2). Such gear was found on many locations in the world and has been used frequently up to the present. The oldest harpoon head, found in East Africa, is about 90,000 years old.

Another ingenious invention was a spear-throwing instrument, later called *atlatl* by the

Aztec of Mexico, which was distributed widely over all continents (Fig. 3). The oldest known atlatl was used in northwestern Africa 25,000 years ago; Australian aborigines still hunt with similar tools today. The atlatl was increasingly replaced by bows and arrows, known in Europe since 25,000 BCE, and in America since about 2,500 years ago. Many native people even today fish with this technique.

Fishing in the Stone Age, Fig. 11 Fishing with tamed cormorants. *Above:* An old method used in China (Dabry de Thiersant, 1872); *Below:* Drawing from a ceramic receptacle from the Moche culture, 100 BCE-700 AD in Peru, exhibited in the Museo Amano, Lima (drawing Sahrhage)

Angling may have started during the latest glacial epoch with the gorge, a little wooden stick, pointed at both ends, with a ring furrow for fixing a line (Fig. 4). Curved fishhooks seem to appear only after the Ice Age in the subarctic hunter civilizations of northern Eurasia from where this method spread out to Europe and to the Far East and America (Fig. 5).

With major climatic changes around 12,000 BCE, large parts of the ice cover melted and the sea level rose in all the oceans. Wide coastal areas were flooded and many valleys and depressions filled with water. People

changed their activities increasingly from hunting to fishing with subsequent improvements in catching techniques (Fig. 6). Temporary, and later permanent, settlements on rivers, lakes and the seaside developed where fishing possibilities proved favourable. Dense concentrations of prehistoric fish, seal and whale remains, and huge heaps of shell middens in many places of the world indicate the great importance of aquatic fauna as human food (Fig. 7).

Remains of fishnets lasted only under special conditions in swamps and arid deserts. Knowing how to knit netting marked a major form of progress (Fig. 8). The oldest nets, excavated in Finland and Peru, are 9–10,000 years old, but the history of nets may go back far earlier. In the Czech Republic 27,000 year-old impressions in clay were found which seem to originate from net meshes.

Many rock paintings and engravings certify the role of fish in the spiritual life of Stone Age people, possibly during magic rites in shamanism (Fig. 9). This is evident also from X-ray images found in Europe, northern Asia, America and Australia, showing the inner organs of the animals (Fig. 10).

A sophisticated technique of fishing developed in China, Japan and Peru, where cormorants were tamed to deliver their fish prey to the fisherman who took care of the birds (Fig. 11).

Probably rather early, people started to build vessels for crossing the waters and reaching aquatic resources in deeper areas. For this they used the materials locally available to produce, for example, reed rafts in swamps, dugout canoes in forest regions (Fig. 12), and boats with skin hulls stabilized by wooden sticks.

Various methods of fish preservation were also developed during the Stone Age: drying over the fire or in the wind and sun to produce stable food for the long winter periods passed mostly in caves, and for migrations, as well as salting and pickling.

Most of the basic types of fishing techniques originated in the Stone Age. They are still widely applied.

Five Phases (*Wuxing*)

Ang Tian Se

Five phases, or *Wuxing*, is one of the basic concepts used by the ancient Chinese along with *Qi*, *Yin*, and *Yang*, to explain natural phenomena. The term *Wuxing*, formerly translated as “Five Elements” is now rendered as “Five Phases”. The reason for such a rendering is simply that the term *Wuxing* in Chinese did not necessarily mean

“Five Elements” as we understand them today but is a term which implies something dynamic, ever moving, and transforming in a regular pattern through the operation of *Qi* in nature.

Before we trace the origins and development of the *Wuxing* concept, we should bear in mind that early Chinese thought was perennially involved with the relationship of humanity and nature. Humans were seen to hold an integral but not an assertive place in nature. They had to understand nature and live harmoniously with it. To provide a rationale for it, *Zou Zhuan* (Master Zou’s Enlargement of the Spring and Autumn Annals) of the fifth century BCE says:

There are Six *Qi* in nature. When they descend, they give rise to the Five Tastes; display themselves in the Five Colors, and are evidenced by the Five Sounds. When they are in excess, they generate the Six Diseases. The Six *Qi* are *yin* and *yang*, wind and rain, dark and light. They divide to form the Four Seasons, showing the Five Periods in sequence. When they are in excess, they bring about calamities. Excess in *yin* results in cold diseases; excess in *yang*, hot diseases; excess in wind, the diseases of the extremities; excess in rain, the diseases of the stomach; excess in dark, delusions; excess in light, diseases of the heart.

Realizing that nature is vicissitudinary, the early Chinese classified, through their observations and experiences, all the natural phenomena as well as mundane affairs in groups of fives. Classification as such was based on their perception of nature and the society in which they lived. Hence, in several pre-Qin (third century BCE) texts we come across such terms as *Wufang* (Five Directions), *Wushi* or *Wuchen* (Five Periods/Seasons), *Wude* (Five Powers), *Wucai* (Five Materials), and other fivefold categorizations. The oldest reference to the term *Wuxing* without the nomenclature for the set of five is found in the *Guo Yu* (Discussion on the Ancient Feudal States) of Western Zhou in the eighth century BCE.

The person purported to have systematized and stabilized these ideas of categorization was ► **Zou Yan** who flourished between 350 and 270 BCE. He referred to the set of Water, Fire, Metal, Wood, and Earth as “Five Powers”. He cited the rise and fall of past dynasties to put

forward a cosmological theory of monarchy. As a reflection of the order on Nature, the political order was subject to the Five Powers which conquer each other. This sequence later came to be known as the Mutual Conquest Order (*Xiang Ke* or *Xiang Sheng*), wherein Water conquers Fire by extinguishing it, Fire conquers Metal by melting it, Metal conquers Wood by cutting and carving it. Wood conquers Earth either by digging it up or growing out of it, and Earth conquers Water by damming it up and constraining it. Because the Five Powers dominate alternately, it is seen that the process of domination is itself “controlled” by the Power which conquers the conqueror. For example, Wood conquers Earth, but Metal controls the process. There is yet another sequence which is found in the *Chun Qiu Fan Lu* (String of Pearls on the Spring and Autumn Annals) by Dong Zhongshu of the second century BCE. The sequence gives rise to the Mutual Production Order (*Xiang Sheng*), in which the Five Powers generate each other. The sequence begins with Wood which produces Fire (being consumed as fuel). Fire produces Earth (by forming ash), Earth produces Metal (by fostering the formation of metallic ores), Metal produces Water (by liquefying itself when heated), and Water produces Wood (by nourishing the plants). If both the orders of Mutual Conquest and Mutual Production are taken together, it is seen that in the process of destruction of one Power by another, the process of change is somehow “masked” by some other process which produces more of the substrate, or produces it faster than it can be destroyed by the primary process.

Another *locus classicus* of the pre-Qin period which describes the Five Powers as Five Processes is found in the *Hong Fan* (Great Plan) chapter of the *Shu Jing* (Historical Classic). The text gives the names of *Wuxing* in numerical order, followed immediately by their respective descriptions. Thus, we have:

- Water: wetting, descending
- Fire: flaming, ascending
- Wood: (allowing to be) carved, straightened
- Metal: (allowing to be) molded
- Earth: sowing and harvesting

The description suggests five sorts of fundamental processes characterized by their respective quality in nature.

In their effort to understand the physical changes in Nature, the early Chinese tried to establish a viable system in terms of abstract ideas. In the *Wuxing* chapter of *Guan Zi* of the late fourth century BCE, the set of Wood, Fire, Earth, Metal, and Water is fitted to 72-day divisions to the 360-day year in order to show the change of seasons in an evolving manner. The set of five is associated with five types of *Qi* that bring about changes in nature. Then, in another *Wuxing* chapter in *Bai Hu Tong* (Comprehensive Discussion in the White Tiger Hall) of the first century, the word *Xing* is specially used to mean “the activity of *Qi* by the natural order.” In the *Chun Qiu Fan Lu*, too, *Xing* means “activity”. It is clear that *Wuxing* is no longer seen as a set of chemically or physically distinct substances, nor is it a force itself which is capable of performing actions. The *Wuxing*, then, are phases of change brought about by *Qi* in Nature.

Food and the Maori

Jim Williams

University of Otago, Dunedin, New Zealand

The New Zealand archipelago spans from 35° to 46° South and, accordingly, offers a wide range of soils, climates, and, therefore, growing seasons. The result is a range of diets based on two predominant zones. In the northern three-quarters of the country, kūmera [sweet potato] provides the carbohydrate staple and has achieved a higher status in this area than in any other region of Polynesia; in the southern quarter, kūmera will not grow and a quite different lifestyle evolved, primarily based on hunting and gathering. It is this region that is here analyzed.

In 1879, in preparation for a Royal Commission into South Island land sales, southern Member of Parliament, H. K. Taiaroa, interviewed the oldest folk around to collect details of the regular food-gathering journeys to 1479 sites and the 114 associated foods.

Of the 114 food items, 57 are sources of protein, including 12 of the 20 most commonly encountered (Fig. 1).

Half of all sites were sources of tuna, or eels, the ubiquitous source of protein and fat, available from September until April. Weka is a flightless bird approximately the size of a chicken and a prominent winter standby when it was at its best. Aruhe, or fern root, provided a poor source of carbohydrate, mainly eaten for bulk. Inaka, kokopu, panako, koukoupapa, and pipiki are

Food and the Maori,
Fig. 1 The most
 commonly encountered
 foods

native freshwater fish. Kāuru is an especially rich source of fructose (carbohydrate), extracted from the rhizome of a tree lily known as tī. Kāuru is extracted from the root of the so-called cabbage tree in spring, when its polysaccharide content is highest (greater than either sugar cane or sugar beet). Aruhe, the root of the bracken fern, was a poor sort of carbohydrate and boring to eat, so it was flavored with mineral-rich juices. Tutu juice was high in vitamin B; korari, or flax nectar, was high in niacin and agar, extracted from seaweed, provided iodine. Waterfowl, forest birds, and kiwi, as well as the rodent, kiore, also provided protein and fat. Pora, tutu, and koareare are vegetables and provided vitamins and minerals.

The protein foods were not only the most numerous, but many were available in sufficient quantity to be preserved. Such variety provided choice, and cultural factors emerge. The majority of *kai wairua*, or prestige foods, are protein foods (or combinations of protein and fat). The main fatty foods, tuna and tītī (muttonbirds), both sources of Omega-3 fat, were available in their greatest quantities in late autumn and early winter and were therefore of special value as energy can

be temporarily stored as fat in the adipose tissue for use in the forthcoming period of relative shortage. Subsidiary sources of fat were also popular when preserved. However, it is kāuru that stands out, particularly in the southern three-quarters of the region. As the main source of carbohydrate, great quantities of kāuru were prepared and Tikao (n.d.) details how every hapū, or subtribe, held a *kaihaukai* (a form of ritual feast with the emphasis on reciprocal food exchange) for its neighbors when the kāuru was harvested. There is no record that kāuru was preserved (in fact, Tikao mentions the tendency for it to go moldy (*waitautia*) (n.d., p. 7)). It was harvested in quantity and seems to have been consumed within a quite short time. A feature of kāuru consumption is the number of confections based on it; Tikao mentions fruit juices used as flavorings, as well as a type of jelly made with agar.

Diet

There is little firm evidence to support detailed traditional knowledge of nutritional values; yet

Food and the Maori, Table 1 Approximate composition of shellfish with highest gross energy

Species	Protein	Fat	Carbohydrate	kcal	kJoule
Tuatua	16.7	2.2	6.2	110	460
Bluff oyster	12.9	3.0	3.1	103	429
Pāua	20.8	1.0	0.9	99	415
Rock lobster	21.9	0.8	0.7	97	408
Kina (sea egg)	10.8	5.4	0.6	94	394

Food and the Maori, Table 2 Approximate composition and gross energy of fillets of finfish

Species	Protein	Fat	Carbohydrate	kcal	kJoule
Barracuda	19.3	3.3	*	107	447
Blue cod	18.1	0.8	*	80	333
Snapper	19.4	1.6	*	92	385

the balance in the diet, and particularly the use of tuatua (a type of clam) as a food of last resort, strongly suggests an innate understanding of dietary needs.

The importance of carbohydrates and fats (Speth and Spielmann (1983, p. 13) say that carbohydrate is much more efficient than fat for converting excess protein to energy) in the human diet is well known, as is the necessity for a balanced diet. Pre-European Māori appear to have had an intuitive understanding of dietary requirements. Eating patterns, as indicated by dietary preferences (allowing for some “taste” items), seem to be largely consistent with nutritional needs in that most provide a key dietary element. “[It has been shown that] if the body lacks some chemical, the individual will tend (in an imperfect way) to develop a specific appetite or partial hunger for that food element” (Maslow, 1954, p. 81). Johns (1990, p. 17) comments: “humans develop specific appetites related to nutritional deficiencies such as salt, iron and vitamins.” The Māori language recognizes this aspect. In the idiom used by speakers of Māori and others who use the same idioms, when translated to English: “I’m hungry for a feed of (e.g.) oysters (or ice cream) etc.” Folk who are simply hungry are likely to say “I’m hungry for a kai (or feed).” This is of interest for two reasons. It illustrates that during most seasons, there were dietary choices and, in addition, that the people knew which foods were vital at the time.

Nutritional Balance

Vlieg provides two tables: “proximate composition of shellfish (g/100g wet weight)” (1988, p. 47) and “calculated gross energy of the edible part of shellfish” (1988, p. 50), from which data for the five shellfish with highest gross energy have been extracted and conflated in Table 1 above.

For comparative purposes, the three most favored finfish species (data from Vlieg, 1988, pp. 23–36 and pp. 48–49) are shown in Table 2.

With the exception of tuatua, all are favored Māori traditional foods and even today are strongly preferred, except that tuatua are not particularly popular. But of special interest is the fact that tuatua have the highest energy levels of all (even including finfish). To claim a relationship between dietary preference and nutritional value, the enigma of the tuatua must first be resolved. Perhaps, the key lies in its relatively high carbohydrate level which, in line with Speth and Spielmann’s assertion, would be invaluable in facilitating the conversion of excess protein into energy at times of plant carbohydrate shortage.

Tuatua does feature in archaeological sites, but somewhat enigmatically and sporadically over time. Anderson (1983), who recognizes three periods of food intake, says during “the Early (Moa Hunting) Period: AD 900–1350 . . . Shellfish account for no more than 5–10 % of the total [intake of animal food]” (1983, p. 16).

During the Middle Period, AD 1350–1550, fishing became the major activity and “it provided 31 % of the food represented in the late (14th century) occupation level at Pounaweia and 89 % of that at 14th century Purakaunui” (1983, p. 26). By the Late Period 1550–1800, further adaptations had taken place and shellfish became relatively unimportant. Even at Pounaweia, where fishing was long the major contributor to the diet, dense layers of *tuatua* shell tend to be interspersed with layers having few *tuatua*. This could mean that *tuatua* were only available in some years or were eaten when preferred foods were not available. Shortages of *tuatua* appear unlikely and the latter hypothesis is preferred. It is supported by Leach, Davidson, Robertshawe, and Leach (2001, pp. 22–23) and confirmed by elder Te Mahana Walsh of Kāti Huirapa, who said “the old people only ate *tuatua* when there was nothing else. They didn’t really like it” (pers. com., 1994).

It may be argued, as Carson does in the case of *umu tī* in island Polynesia, that “use only in times of famine still constitutes a food restriction” (2002, p. 346), but when the major determinant is taste, the argument does not hold up. Rather, the avoidance of *tuatua* except in times of hardship demonstrates a range of choices that allowed taste preferences to be indulged.

Underlying this issue is the question as to what such a preference might be based on. According to Vlieg, “The principal carbohydrate in fish (glucose) is not very sweet, and flavour appears mainly due to the presence of non-protein nitrogenous compounds” (1988, p. 6). But Simpson considers that conventional definitions of “flavor” are too narrow in that “Texture and colour have always played a major role” (1982, p. 115) and that aroma is one of that group of properties, usually referred to as flavor, which either attract or deter the consumer.

Sea mammals, which archaeological evidence suggests to have been the major source of fat in the early prehistoric period, were rarely consumed after the mid-fifteenth century (Anderson, 1983, p. 24). Soon afterwards, *umu tī* seemed to proliferate (Anderson, 1983, p. 26), and these foods continued to be of primary

importance until the middle of the nineteenth century (Shortland, 1851, and see the data from H. K. Taiaroa in this article). This is likely to have been the main source of carbohydrate, and *tītī* and tuna, neither of which leave remains that persist in archaeological sites, were likely to have been of considerable importance as sources of fats and oils. The prevalence of *aruhe* sites in the Taiaroa (1880) lists suggests that it, too, was probably of some importance, especially as a food of choice while traveling, due to its being widely available, as well as light to carry. It may also have been a staple in times of food shortage.

Food Values of “Principal Foods”

For current purposes, “principal” foods are those eaten in large quantities and “primary” foods are the primary target of a food-gathering journey. There is considerable overlap between the two. It is instructive to examine the value of items of food that were eaten or stored in large quantities:

Mata, or whitebait, are “essentially similar” to other fish species for lipids (Sumner & Davis, 1977); it has not proved possible to check their carbohydrate values and *makā* (*barracouta*) are “not exceptional in any significant way” according to Pickston, Czochanska, and Smith (1982, p. 25). Accordingly, it would seem that both were taken in great quantities due to their availability, ease of drying, and, perhaps, taste, but probably not for any nutritive reason.

Kāuru is exceptionally rich in carbohydrate. Fankhauser, in his study of the nutritional value of *kāuru*, comments that it was equivalent to taro or yam in carbohydrate content and richer in sugars than either sugarcane or beet (1986, p. 184).

Tuna has a lipid content that increases with the size of the animal, from 6 % in 70 g eels to 22.7 % in 820 g eels (Sumner, John, Hopkirk, & Glen, 1976). “During maturation the eel deposits additional fat evenly along its length” (Wills and Hopkirk, 1975, p. 526). They comment further that other than this increase with size (weight), there is no discernible

difference between the sexes or between the species. Nixon points out that “Two components contained in eel which are of considerable significance for Maaori health are the omega-3 fatty acids and lecithin” (2001, p. 133). She goes on to discuss the dietary significance of these components that offset the known deleterious features of fatty diets, such as high cholesterol, to the extent of having a number of advantages to the human circulatory system. In addition, Graham quoted Dr. M. Cunningham who reported that “whole-fish oil from the eel is found to have a Vitamin D content equal to that of a moderately good Cod-liver oil” (1974, p. 131).

Kiore, too, were preserved in their fat. Taare Te Maihāroa related to Maud Hayter how they were caught in large numbers in the MacKenzie country. They could also be “grilled on a stick,” like a kebab, and eaten bones and all (Aubrey, 1978, p. 52).

Tuatua, as has been pointed out, were rich in both carbohydrate and fat and were readily available, but important only as a “food of last resource” (see Leach et al., 2001 for an extensive discussion).

It is argued that kāuru, titi, and tuna were the most important foods nutritionally and, therefore, should present the best opportunity to assess the relationship between economic and environmental values.

Principal Foods

The term used by most writers for principal foods is “staple,” but views differ among experts on what constitutes a staple food. This may be because principal foods can differ from place to place and season to season. Anderson (1982, p. 61) says that staples such as kāuru, tuna, and aruhe may be de-emphasized in favor of more valuable (or highly favored) foods for exchange. However, the fact that kaihaukai were held for kāuru suggests that it is also in the valued category, and tuna, while available in most areas,

were certainly exchanged by the people of Wairewa and Waihora where there were excesses, as they were seen as “kai wairua.” So, we should not view “staple” and “valuable” as mutually exclusive terms.

There were a small number of foods like Anderson’s (1982) “kāuru, tuna, and fern root” that seem to have been eaten regularly, and as the principle component of a meal. A great number of other foods are eaten less regularly for reasons of availability, preference, or nutritive value, but which still make a significant contribution to the diet. While all lie along a continuum, some foods are clearly more important than others, irrespective of how often they are eaten, and it is from this that the concept of “primary foods” has been developed. Some were eaten in small quantities, and often, others were eaten only occasionally, but in great quantities; either type had its significance. Smith (1985, pp. 400–402), discussing the nutritional requirements of early Murihiku Māori, observes that even quite a small amount of plant food could have provided balance to their diet.

Primary Foods

Primary foods are defined as those of sufficient importance to be the main target for a harvesting trip. They were harvested in quantities sufficient to provide a surplus for storage and trade. Some may be primary foods at one time of year and of lesser importance at others: tuna were a primary food during the heke (Autumn migration) but enjoyed as subsistence foods in spring and summer.

Important primary foods were inaka/mata, which were dried in the sun (as were a number of other foods). Hāpuku (grouper) were caught in Summer and tuaki in Spring – when they were “milky” – and in each case were dried and set aside for winter (Khyla Russel, 1.12.2003, pers. com.). “Kiore were trapped when berries were ripe, which added to the flavour as well as making them easier to catch” (Bradford Haami, 1992, personal communication). They also caught forest birds and makā (barracouta), a seasonal, shoaling surface feeder, of “up to five feet”

(Green, 1975, p. 617) and 8–10 lb (Graham, 1974, p. 315). The main season for makā, March, came at the end of the summer season when the focus had been inland and immediately prior to the muttonbird season (Anderson, 1981, p. 146). Shoals could be of immense size, as Graham records “sometimes densely occupying many acres at the surface” (1974, p. 313). They were caught in large numbers and cleaned and hung on racks to dry in the sun (p. 315). Because abundance of food was largely seasonal, average population density was determined by the seasons of shortage and not by the occasional peaks in supply.

Further south, tītī (muttonbirds) were the most important food, and in early winter, these were traded throughout the area of this study. In mid-winter, when other foods were scarce, weka were caught and preserved in large numbers but apparently not traded.

Helen Leach, who analyzed late-prehistoric food patterns, commented on regional differences within the South Island. While some major seasonal foods are ignored, the regional differences observed are instructive:

... the inhabitants of South Canterbury consumed quantities of fresh-water fish and cabbage tree roots, the Otago natives lived principally on fernroot, birds and seafish; the Westland Maoris ate mostly freshwater fish and preserved birds and their diet included less vegetable matter than in the east. (1969, p. 75)

The differences are largely associated with key local microenvironments, such as bush-covered waterways or extensive wetlands. However, certain cultural preferences have a regional basis, to the extent that some foods are synonymous with a given area. These, too, can be related to local microenvironments: e.g., tuaki (cockles) at Ōtākou and tuna at Wairewa and Taumutu. Such foods are termed manakai and, in some cases, kai wairua. That is not to say that these foods were not available elsewhere, but there they were not the foods of mana (prestige), symbolic of the mana whenua in that district. Accordingly, a gift of food should not be the food, that is, the manakai, of the recipient except under exceptional circumstances.

Complementarity

That precontact Māori had clear notions of dietary need is attested by the traditional eating of complementary foods, and many of these practices have persisted into contemporary times. For example, Paddy Gilroy (28/7/1998 pers. com.), during a public talk about muttonbirding, said, “tūtae-kōau, or wild parsley (*Apium prostratum*) that grows in sand dunes, it has always been boiled and eaten with tītī.” Christina Macdonald mentions that “it has diuretic and anti-scorbutic properties” (1974, p. 115), a comment on the benefits of tūtae-kōau but without identifying why it was complementary to tītī. In the case of kōuka, the so-called cabbage of the tī tree, and tuna, another complementary pair (Williams & Chrisp, 1992), the active ingredient is identified as ascorbic acid, an agent that aids in the digestion of fats. John Moorfield, too, recalls a meal of “blind eel and kōuka” at Tokomaru Bay, in the 1980s (2.4.2001, personal communication). A reasonable inference here is that the people felt comfortable when certain foods were eaten together, whereas heavier foods, on their own, were less easily digested. Perhaps the same principle has led to the contemporary partiality for pork and pūhā (sow thistle).

Extant Foods

Of the principal foods mentioned, only tītī, tuna, and mata/inaka are significant today. Tītī remains the food of greatest overall significance. Pora is extinct, and kākāpō and kiore have been exterminated from the study area. The galaxiids are now threatened species due to habitat reduction and the predations of introduced salmonids. Weka, kiwi, and the forest birds are also rare, due to the combination of reduced habitat and introduced predators. Poisoning for rabbits has also had a significant impact on weka. Tutu has been virtually extirpated due to its toxicity to stock, though there is anecdotal evidence of a small revival of interest in the beverage. Waterfowl are now subject to Fish and Game Council licensing and most Māori harvests conform with the

exigencies of duck-shooting season. Nevertheless, a few families do continue a tradition of taking māunu (this term may apply to fledglings or adult ducks during the late summer molt). One family advises that this practice has been followed since traditional times, but in a limited form. Only one meal per season is taken, comprising no more than three ducklings per brood, to an overall total of six, one each for the members of the family involved. At this quantity, the harvest is a token: no more than an annual assertion of ahi kā (traditional stewardship). Aruhe, kāuru, and kōareare are no longer sought after.

Food Production Systems in the Amazon

Rodrigo Sierra
Cedar Park, TX, USA

The following discussion focuses on productive systems found in riverine and interfluvial forest environments, which cover approximately 75 % of the Amazon Basin (i.e., not in wetland, savanna, or shrub environments, such as Cuyabeno, Beni, or Cerrado, respectively). The Amazon has 12 major river basins covering approximately 7.8 million square kilometers,

most of which (~65 %) are in Brazil. Other countries sharing the Amazon are Peru (~10 %), Colombia, Bolivia, and Venezuela (~6 % each), Guyana (~3 %), Surinam (~2 %), Ecuador (~3 %), and French Guyana (~1 %) (RAISG, 2012).

The conventional definition of food production systems revolves around the growing of food plants (Piperno & Pearsall, 1998). This definition, however, is insufficient to describe the main sources of food in the Amazon. Amazonian food production systems, like the Amazon itself, are very diverse. These include activities involved in the growing of food plants, the production of plant foods from foraging for wild and semidomesticated plants (e.g., roots, fruits, nuts), and animal foods, through hunting, fishing, and gathering (e.g., of iguana and tortoise eggs, stingless bee honey, beetle larvae from palms). Historical evidence suggests that the importance and characteristics of each activity have varied from place to place and from period to period. For contemporary traditional Amazonian societies, for example, Carneiro (1970) estimated that the Amahuaca, an isolated group in the central Peruvian Amazon, spent as much time hunting as working on horticulture and that the former generated about 40 % and the latter 50 % of the food consumed. In contrast, the Akuriyo of Suriname seem to have persisted without agriculture, mainly from hunting, fishing, and gathering (Kloos, 1977). In some areas, fishing is an important component of the diet, with families consuming wild fish at least once a day (Dorea, Barbosa, Ferrari, & De Souza, 2003), while in others hunting is more important (Suárez et al., 2009). Beckerman (1987) found great variation in the dependence on horticulture in the diet of 34 indigenous groups, ranging from over 80 % among the Bari and Kuikuru to equal or less than 50 % among the Amahuaca and the Secoya.

Amazonian food production systems developed in three phases: Paleo systems, or systems that dominated before the diffusion of agriculture; traditional systems, or systems that incorporated indigenous agriculture (crops, technology) as a major source of food; and contemporary systems, or systems that incorporate elements of

old-world food production systems. None has completely disappeared or dominated others; they coexist in different forms in today's food production systems. Contemporary systems considered in this article are those used to produce foods for consumption and the production of crops, such as coffee or rice, in small-scale mixed commercial-subsistence, generally family, systems. Medium- and large-scale commercial production and producers of animal products, cattle in particular, and crops, such as soya and oil palm, are not discussed here.

Paleo Systems (Pre-Agriculture)

Humans have lived in the Amazon for at least 11,000 years (Roosevelt et al., 1996). The oldest record of human habitation in the Amazon was found in Caverna da Pedra Pintada, Brazil, dating 11,000 years before present (YBP) (Roosevelt et al., 1996). Physical differences between early and current Amazonians suggest that at least two major waves of occupation occurred, Caverna da Pedra Pintada being an example of the first wave. Early Amazonians seemed to have produced foods from wild and semidomesticated plants (fruits, nuts) and from animals, through hunting, fishing, and gathering. Human groups were probably highly mobile in response to the depletion of preferred preys (Gross, 1975) and the large natural stock fluctuations of animal foods (Sponsel, 1986). Similar to other paleo-American societies of this time, there is no evidence that paleo-Amazonians practiced any significant form of agriculture. Blowguns and darts, spears, and bows and arrows, probably made of palm wood, were used for hunting. Figure 1 (e.g., see www.childrenoftheamazon.com/wp-content/uploads/2010/04/bow-and-arrow-surui-village.jpg). Spears may have had sharpened bone or stone heads. Some groups probably poisoned their arrows or darts with mixtures of animal and plant compounds.

Gross (1975) postulated that animal protein limited human carrying capacity in Amazonia, suggesting that original populations had to be small, dispersed, and mobile. This logical-economic

Food Production Systems in the Amazon,

F

behavior is predicted by optimal foraging theory (Alvard, 1993; Hames, 1987; Kaplan & Hill, 1992). Foraging theory is a branch of evolutionary theory that has been used to examine the behavior of food production and livelihood strategies in a wide variety of taxa including humans. The periodic replacement of extraction areas, primarily for hunting, can be conceived as a strategy to maximize the efficiency of the foraging effort (Winterhalder & Smith, 2000), where frequently moving the foraging area, once low productivity is reached when compared to an expected local optimum, rather than waiting for a zero return to move, ensures a minimum acceptable return per unit of effort. However, Beckerman (1979) argued that for hunter gatherers, fruit trees, producing either nuts or seeds or starchy, oily, or juicy pulps, were likely sources of protein and important components of their diet, allowing higher densities and less mobile populations than Gross' postulate would predict.

All known indigenous groups who dispense of agriculture to produce food are highly mobile, have low population densities, and live in relatively small groups. Theirs are not necessarily remnants of paleo systems because it is possible that they reappeared after a period of agricultural development, as fearful indigenous populations continuously ran away from the diseases and slavery that came with the arrival of Europeans.

They are, however, probably similar in function as the environment and technology available were also similar. For example, the Akuriyo of Suriname (Kloos, 1977) and the Maku and Nukak of Colombia (Politis, 2007; Silverwood, 1972, respectively) persisted mainly from hunting, fishing, and gathering. These groups do not use agriculture as a source of food, changing residence periodically within a relatively stable area, requiring larger areas compared to populations that use agriculture to produce food. Analysis of hunting preferences show that some types of animals are preferred and that for each type, larger prey is preferred (Peres & Palacios, 2007). According to Carneiro (1970), for example, the Amahuaca, a Peruvian group that depends on hunting for a significant part of their diet, hunted and ate most large animals (tapir, large monkeys, peccary, guans) but did not eat carnivores (jaguars, pumas, eagles, vultures) and a few noncarnivores (giant armadillos, raccoons). Amahuaca hunters learned "every significant detail of the life habits of game animals." Individual males carried out most hunting, although meat was often shared with kin and friends. Gathering of nuts, fruits, and other food from forests was primarily done by women.

These are groups that today are extremely rare. If lack of contact with outsiders is a direct indication of their mobility, and mobility an

indirect measure of their dependence on hunting, fishing, and gathering (as opposed to agriculture), there would be approximately 50 such groups in the Amazon today (i.e., the approximate number of uncontacted peoples) with a total population of a few thousands. Of these, the majority are found in the Brazilian Amazon, 20 in Peru, and equal number in the remaining Amazon countries (Pantone, 2008; Watson, 1996). Many of these occur in two or more bordering countries.

Traditional (Precontact) Systems

It is generally accepted that the population of Amazonia at the time Europeans arrived was between 5 and 10 million (Denevan, 1976; Roosevelt et al., 1996). The first European accounts of life in the Amazon by Priest Gaspar de Carvajal, c. 1540–1542, described large areas along major rivers with what seemed to be stable high-density populations, with widespread agriculture, including the husbandry of native animals (e.g., tortoises), separated by unpopulated areas between them. Friar Carvajal's narration also included Amazons, mythical warrior women that gave the name to the region, and other hard-to-believe or too-convenient events, and for these the literal meaning of his story has been doubted many times. In this case, however, the concentrated distribution of the population is consistent with other evidence, such as the concentration of Anthrosols (soils that have been improved by human activity) and of domesticated plants, dating as far back as 2,500 YBP to soon dating as far back as 2,500 YBP to soon after the arrival of Europeans. Most people probably lived on the floodplains of large rivers and depended on a combination of semipermanent agriculture, hunting, fishing, and gathering to sustain semi-sedentary, relatively high population densities (McMichael et al., 2012).

By the end of the sixteenth century, many European visitors described Amazonians as lacking agriculture. Pollen and charcoal records also suggest that populated sites were abandoned in the southern Peruvian Amazon at more or less this time (Bush, Silman, & Listopad, 2007). It is

possible that semipermanent agriculture and dense populations became rare in the Amazon as European diseases and abuse rapidly decimated local populations. To avoid these threats, many of the remaining groups probably regressed to more mobile food production systems, with less intensive agriculture, in the interfluvial hinterland (Cleary, 2001). Murdock (1967) listed the average population of the settlements of 30 Amazonian groups in the mid-twentieth century; of these, 24 had fewer than 100 people.

Agriculture in South America began with the domestication of native plants in various places at various times, with the oldest agricultural sites, dating from 13,000 YBP, found in Norte Chico in coastal Peru (Mann, 2005). In the Amazon, the earliest signs of domestication of plants date to 7,000 YBP, but there are not known indigenous domesticated animals. Widespread animal husbandry, of tortoises and birds, for example, was observed by the European visitors just 50 years after their arrival in America, but these animals also occur commonly in the wild. In the Beni savanna, people constructed large networks of earthen fish weirs suggesting that intensive seasonal fishing was key for their survival (Mann).

By 2,000 YBP, there are clear indications that agriculture was widespread and sustained (Sombroek et al., 2002). Reports of the number of domesticated plants used for food at the arrival of European explorers easily surpass 130, more than half of which are trees (Clement, de Cristo-Araújo, Coppens d'Eeckenbrugge, & Alves Pereira, 2010). The majority seem to have originated in the Amazon, but others probably came from the Andes and even Mesoamerica (e.g., maize, cacao). Manioc or cassava (*Manihot esculenta*) and maize (*Zea mays*) seem to have been key crops since very early in the occupation of Amazonia (Clement, 1999). Manioc, the most important staple in the Amazon, is a root that probably came from and was domesticated in the Cerrado (dry) Sabana possibly as early as 10,000 YBP. Manioc is an incredibly versatile crop used to cook, to make flour, for various types of beverages, and other uses. Peanuts (*Arachis hypogaea*), papaya (*Carica papaya*), pineapple (*Ananas comosus*), avocado (*Persea*

americana), Achira (*Canna edulis*), sweet potato (*Ipomoea batatas*), and passion fruit (*Passiflora edulis*) also originated within the Amazon. In many areas, semidomesticated palms, like the chonta or pejiyabe (*Bactris gasipaes*), were also important (Clement). Clement hypothesized that crop diversity is correlated with sustained human occupation of an area and that the productivity of domesticated plants and semidomesticated animals determined the population density potential of an area; hence higher densities would tend to occur where there has been long human occupation. Some researchers have also assumed that there is a close relationship between crop genetic diversity and cultural development (Vavilov, 1992). Higher traditional food diversity has been associated with greater protein, fiber, vitamin, and mineral intakes (Roche, Creed-Kanashiro, Tuesta, & Kuhnlein, 2007).

Indigenous farmers may have practiced crop selection methods to improve the quantity and quality of their harvest. Kerr and Clement (1980) describe the custom among the Ticuna Indians near Leticia, Colombia, of distributing among households in a group edible crops or fruits that were especially large or flavorful. The Kayapó of the Brazilian Amazon are known to promote the growth of forest patches with high concentrations of useful plants on open lands by a form of composting that uses termite and ant nests mixed with mulch (Posey, 1985a). The Yamuesha, in Peru, collect, trade, and maintain preferred crop varieties while purging the less desirable types (Salick, Cellinese, & Knapp, 1997).

Agriculture also requires the development of appropriate techniques for soil and crop management and storage, some of which are still visible in the archaeological record and surviving traditional food production systems. The best known is probably the development of fertile Anthrosols through controlled burning; this is discussed below. Denevan (2002) reviews traditional techniques used in the Amazon to control pests and weeds, crop rotation and storage, soil and site selection, and ground preparation. As noted above, amazonian farmers also developed techniques to grow wild animals and to fish them in

large quantities. In the first recorded travel of the Amazon River by Europeans, Fray Gaspar de Carvajal described tortoise pens in the settlements the troupe of Spaniards led by Capt. Sebastian de Benalcazar raided for food. Sombroek et al. (2002) report Anthrosols patches every 5 km along the Igarapés River in southeastern Amazonia. Agricultural plots had probably long fallow periods after years of planting, but fallow may not have meant plot abandonment but rather managed forest regrowth to create forests with high concentrations of useful plants (Denevan, 2002). Denevan estimated the population density of the Amazon floodplain could have reached hundreds per square kilometers, compared to 0.1 person in upland forests.

The main tool for clearing forests to establish traditional agriculture was the stone axe. Tools for weeding and planting were also made of wood and stone (Denevan, 2002). Stone axes were also used for obtaining wood for cooking, building houses, and making canoes. Tree felling was aided by ring-barking and controlled burning. Especially large trees were left standing. Other tools were used for picking fruit from trees (e.g., the garabato, a long flexible stick with a notched end), planting (digging sticks and footplows), and undergrowth and weed clearing (macanas, a wooden club). Mulching was probably used to protect crops from direct sunlight, maintain humidity, and control erosion and fertilization. In the Beni savanna, fire was used to maintain and expand the grasslands, where otherwise forest would have developed (Mann, 2005).

The dependency of agriculture on stone tools probably meant that clearing mature forest for setting up agricultural plots was a daunting task. This means that settlement sites were probably kept as long as possible and that, when necessary, secondary, lighter forest regrowths were preferred for clearing. This is consistent with the continued occupation of sites and explains the high concentration of charcoal and nutrients in Amazon's Anthrosols (black and brown soils) discussed below.

The location of the archaeological record indicates that indigenous farmers distinguished the

horticultural potential of the soils at their disposal and managed them accordingly. This knowledge is still evident today. For example, the Shipibo distinguish at least six soil types, generally using plants as indicators (Behrens, 1989). Around settlements, sites with best soils were kept either planted or fallow but rarely allowed to become a forest. Here, production can be sustained over 50 % of initial levels for over 10 years. In poor soils, production falls by more than 50 % in the second year of use. Carneiro (1970) estimated that the Amahuaca, an isolated group in the central Peruvian Amazon that relied at the time almost equally on hunting and horticulture to produce food, moved their settlements once every year or two within a larger but relatively stable area.

In general, Amazon soils are poor, with areas of naturally occurring good soils along rivers rich in sediments (often originating in highland areas, like the Pastaza Fan) or dark (black or brown) anthropogenic soils (Anthrosols, Amazonian dark earths) found in relatively small patches (up to 500 ha) on river bluffs. Lopez and Sierra (2010) compared horticultural systems in isolated Achuar and Shiwiar communities in relatively good riverine soils and poor interfluvial soils in the Western Amazon. Despite similar family sizes (approximately 7.2 and 7.7 persons/family) in both environments, in riverine environments horticultural plots were slightly larger (average of 3.7 vs. 2.7 has), fallows were significantly shorter (average of 6.9 vs. 20.3 years), productivity per hectare much higher (713 vs. 257 kg/ha/month), and, as a result, each hectare planted sustained more people (average of 9.9 vs. 5.6 persons/ha of cultivated land). Similar fallow cycles have been described for the Tukano along the Vaupes River in Colombia and Brazil (Chernela, 1989, in Denevan, 2002).

Anthrosols were probably created and maybe maintained intentionally over many generations (Neves, Peterson, Bartone, & Dasilva, 2003). There are two general types of Anthrosols: black or dark, occurring generally with pottery debris, probably developed over time in settlement areas; and brown, without pottery debris and a tendency to occur around back soils,

probably developed in horticultural areas. In these soils, nutrient leaching is minimal, soil organic matter is typically double, crop productivity can be several times greater, and fallow periods shorter than in the typical Amazon soil (Lehmann, Pereira da Silva, Steiner, Nehls, & Glaser, 2003; Major, Dittommaso, Lehmann, & Falção, 2005; Sombroek et al., 2002). Petersen, Neves, and Heckenberger (2001) reported that Amazonian dark earths in Açutuba were under continuous cultivation without fertilization for over 40 years.

In densely populated areas, households primarily used a form of agroforestry, with small clearings for sun-demanding crops, such as manioc, and canopy management for species that perform better in the shade, such as the pejiyabe (chonta, or peach) palm (*Bactris gasipaes*). Crops were probably planted in cleared areas in clusters and followed determined rotation patterns depending on soil fertility. The agricultural plot of traditional Amazonian farmers was diverse but clearly distinct from the surrounding forest. The Kayapó, in Brazil, for example, have fields arranged into three concentric zones, each with different crops and management techniques (Hecht & Posey, 1989, in Denevan, 2002). The central area is cleared completely and burned for planting sweet potatoes (*Ipomoea batatas*). A second ring is planted with a variety of crops: manioc, maize, beans, and others. Around these, bananas are planted.

Small clearings were probably slashed and charred (as opposed to slashed and burned), which would explain the high concentration of charcoal in Anthrosols. (Slash and burn could not explain the high concentrations of charcoal in Anthrosols without pottery.) The narrations of the travels by Spanish priest Miguel Cabello Balboa show that the practice was present soon after the arrival of Europeans (late sixteenth century) in other rainforest areas of tropical America (Cabello Valboa, 1951). Even today, charcoal production is an integral part of swidden-fallow practices in many areas of the Amazon (Coomes & Burt, 1999; Hecht, 2003; Steiner, Teixeira, & Zech, 2004). For example, the Kayapó also use small, controlled fires to improve the fertility of

their swidden plots (Hecht & Posey, 1989, in Denevan, 2002).

The territory used for extractive productive activities (hunting, fishing, and harvesting) is more difficult to characterize due to the absence of direct evidence and the very limited literature on the subject (the emphasis, perhaps because of the relative ease of study, has been on the analysis of indigenous horticultural systems). Some researchers believe that extensive and continued human use shaped the Amazon rainforest, incrusting it with high concentrations of useful plants (Balée, 1989; Erickson, 2008; Heckenberger et al., 2003), while others believe that while some small forest areas may have been managed, most were not (Bush et al., 2007; McMichael et al., 2012). Some basic assumptions can be made based on observations in contemporary Amazonian societies. First, extractive and similar areas are anchored in the settlement areas. Second, the intensity of extractive uses decreases with distance to the settlements. The objective is to minimize the effort per unit of production. Sirén, Hamback, and Machoa (2004), for example, demonstrated that there is a clear preference for hunting near their settlements among the Kichwa of Pastaza, resulting in a strong negative density gradient of game animals around these points. The maximum hunting distances observed were approximately 15 km from the origin, with almost 70 % of the effort occurring within 6 km and 90 % within 12 km. The availability of domesticated animals has an important effect on the use of wild animals. Apaza et al. (2002) found that lower beef and fish prices were correlated with a drop in the use of wild animals among the Tsimane' of Bolivia.

Contemporary (Postcontact) Systems

Excluding the production systems of existing, very isolated or uncontacted groups, contemporary Amazonian food production systems show two distinctive characteristics:

First, the resurgence of indigenous swidden agriculture that increasingly incorporates imported crops and technologies (e.g., bananas

and rice in horticulture, dogs and shotguns in hunting, outboard engines, metal hooks and tilapia in fishing, chainsaws in gathering). This resurgence is to a large extent a consequence of the rapid growth of indigenous population in Latin America, including the Amazon. In Brazil, for example, the indigenous population more than doubled, from 294,000 to 734,000, between 1991 and 2000 (Fundação Nacional do Índio [FUNAI], 2012), although some of this growth can be explained by changes in the self-identification of census responders. (It is important to note that key Amazonian crops were also exported to other regions. Manioc, for example, rapidly became a staple in Africa. Crosby (2003) called this two-directional flow of crops and production systems the Columbian Exchange).

Second, the rapid expansion, mostly in the past half century, and current dominance of nonindigenous production systems incorporating selected traditional Amazonian crops and technologies into an otherwise imported agricultural system. Of the more than 30 million people living in the Amazon that have nonindigenous origins, approximately 40 %, or 12 million, live in rural areas. Government policies in the second half of the twentieth century promoted the migration of farmers from other regions to the Amazon. For example, almost 97 % of the farms in the late 1990s along the Trans-Amazon Highway in the region of Altamira, in Brazil's Pará State, appeared after 1973, and approximately 70 % of the farmers came from another rural area in Brazil (Brondizio et al., 2002; Morán, Brondizio, & McCracken, 2002). Sierra (2000) describes a similar process for the northern Ecuadorian Amazon. Growing urban centers in the region have also been important incentives of the expansion of food production in the Amazon due to their demand for food products and as input-supply and financial centers.

Contemporary Indigenous Food Production Systems

At the turn of the twenty-first century, there were approximately 320 indigenous groups in the Amazon (FUNPROEIB Andes, 2009). Together they controlled almost 2,000,000 km², or 25.3 %

of the basin, in nearly 2,200 indigenous territories (Red Amazónica De Información Socioambiental Georreferenciada [RAISG], 2012). Indigenous territories represented 21.7 % of Brazil's Amazon, 52 % of the Colombian Amazon, and 65.0 % of the Ecuadorian Amazon. In the early twentieth century, there were approximately 734,000 self-identified indigenous Amazonians in Brazil (FUNAI, 2012), 55,000 in Colombia (World Wildlife Fund [WWF], 2005), 320,000 in Bolivia (Amazonia Boliviana, 2006), 330,000 in Peru (Mayor & Bodmer, 2009), and almost 250,000 in Ecuador (Instituto Nacional de Estadística y Censos [INEC], 2015). Of these, the majority live in rural areas. In Ecuador, for example, almost 60 % of the indigenous population lives outside of cities and towns (INEC, 2015).

Among people living in indigenous territories, traditional subsistence food production systems with small commercial elements dominate. The swidden agricultural system known as slash-and-burn, which has become almost synonymous with Amazonian horticultural systems, probably developed and spread with the arrival of metal tools (machetes, axes), replacing the traditional slash-and-char system. The sudden injection of nutrients by the burning of vegetation allows growing crops in suboptimal sites, but these have to be abandoned after a few years. With metal tools – metal axes, machetes, and later chainsaws – the cost of clearing a patch of forest dropped significantly compared to the costs of traditional cycles adapted to stone tools. The rapid loss in fertility that follows slash-and-burn is offset by much easier forest clearing and land availability.

While access and control of different food sources such as cultivable land, fisheries, or wild game can vary substantially among and within indigenous groups, in general, households usually have exclusive rights to use and extract resources from land they have cleared and planted, but once the land is abandoned, these rights revert back to the community. Hunting areas may be separated, but game animals belong to everybody. Fishing areas rarely belong to one household (Bennett & Sierra, 2014; Bremner &

Lu, 2006). In indigenous territories that are close to markets and easily accessible, commercial production tends to outstrip subsistence production. Food production systems often include the commodification of traditional food crops (maize, manioc) and animals (wild fish, pacú farming) and the introduction of non-Amazonian cash crops (rice), fruits (bananas), and animals (chickens, tilapia). Important land arrangements begin to change. In Rukullakta, for example, a group of 17 relatively accessible Kichwa communities who hold their land communally, over 80 % of the land held by households was inherited, and therefore unused land did not revert to the community, although formal land titles do not exist (Bennett & Sierra, 2014).

A survey of contemporary swidden horticultural systems of 34 Amazonian groups by Beckerman (1987) shows that manioc (*Manihot sculenta*) is by far the main cultivar (Fig. 2). Only 5 of the 34, including the Emberá and Shipibo, had a different principal subsistence crop – bananas and plantain – which were not present in the Amazon until the arrival of Europeans. The Bari recognize at least four varieties of banana and one of plantain (Beckerman). Among the Achuar and Shiwiari of the Western Amazon, manioc occupies more than 80 % of the horticultural area (Lopez & Sierra, 2010) (Fig. 3). Plantain is the second most important crop, with nearly 11 % of the area. Commercial crops, like coffee, make up 3 % of the planted area. The Kayapó from Brazil identify several indigenous tubers and medicinal plants that grow well under the shade of introduced bananas (Posey, 1985b, in Denevan, 2002), and the Yanesha of the Peruvian Amazon have incorporated bananas in the traditional crop rotation cycle, after manioc, which replaces maize, and before fruit trees (Staver, 1989). On the other hand, most indigenous modern systems seem to have lost important traditional production technologies, such as the management of fire and ash for improving plot productivity and sustainability.

Beckerman (1987) also provided estimates of horticultural plot sizes for the 34 indigenous groups. In all but four cases, average plot size was below 1 ha, commonly around half a hectare.

F

Food Production Systems in the Amazon, Fig. 2 Leaves of the manioc plant and typical family garden planted by the Achuar of western Amazonia (Photo: R. Sierra)

Families often have at least one plot within a few meters of their home, but they could walk or canoe 10 km or more to reach complementary plots. Horticultural plots may be next to each other (e.g., Shipibo) or separated by forest in various stages of regrowth (e.g., Bari). Among the Achuar and Shiwiar, mean horticultural plot size is 1.4 ha, with a maximum of 4.9 and a minimum of 0.2 ha (Lopez & Sierra, 2010). The

average distance of the closest plot of a family to their house was 200 m, and the farthest plot was 1.3 km from the home. Larger families have larger cultivated areas, and the size of cultivation plots increases with distance to the community, and the density of plots is inversely correlated to their size. The relationship between family size and horticultural area is related to the age of a family. Younger and older families, with young

Food Production Systems in the Amazon,

children or with adult children who probably left the household, tend to have smaller horticultural areas. Middle-aged families, with older kids who can work in the plots, either clearing, cleaning, or harvesting, had the largest horticultural areas. When children are old enough to get married and leave the house to form a new domestic unit, the amount of cultivated area declines. In some cases, parents may redistribute land among their married children, which may reduce the

cultivated area under their control by transferring the rights of use to their children. These patterns show relatively egalitarian rights to land in a community. Other things being equal, and especially soils, all families prefer to have their cultivated areas as close as possible to their home. This preference is predicted by location theory, which says that sources that are visited often are best located near the consumption point. Because it is not uncommon for traditional households to

be made of one husband and more than one wife, smaller plots also allow everyone to have a horticultural area close to home. Generally, management of cultivated areas is the responsibility of married women, which places great value on having easy and fast access to a key source of food.

Contemporary Nonindigenous Food Production Systems

Productive land owned by nonindigenous producers is usually held privately. In the Brazilian Amazon, for example, 77 % of the landowners and 90 % of the land claimed by a person or company in 2006 had a private title, with 90 % of claimers living in their properties (Instituto Brasileiro de Geografia e Estatística [IBGE], 2015). Of these, almost 90 % were family units holding together held 34 % of the land. A survey of three colonization areas in the Brazilian Amazon in the early 1990s by Browder (2002) found average farm sizes of 80.2 ha, 44 % of which were under agricultural use. Pichón (2002) reports average farm sizes in the northern Ecuadorian Amazon to be 46.4 ha. In the early 1990s, almost 5 % of the farmland in the Brazilian Amazon was found in properties smaller than 50 ha, which are likely to be owned by mixed subsistence-commercial nonindigenous producers. Manioc (*Manihot esculenta*) was the most important crop produced, consumed, and probably sold, followed in importance by rice or bananas, both introduced. In farms of this size in the northern Ecuadorian Amazon, Pichón, Marquette, Murphy, and Bilsborrow (2002) reported corn and bananas to be the most important subsistence crops. The area allocated to food production was often less than 10 % of the farm. Commercial crops, such as coffee and cacao, occupied most of the cropland. However, pastures and cattle ranching are the most important productive activity by area. In 2006, almost 60 % of the farmland in the Brazilian Amazon was pastures (IBGE, 2015). Castro et al. (2013) reported a similar proportion for Ecuador. In 2006, there were approximately 26 million heads of cattle in nearly 185,000 farms in the Brazilian Amazon (IBGE, 2015).

At the farm level, production strategies of nonindigenous food producers respond to various factors. For instance, land use intensity increases with increasing access to markets and commodity cycles. In some cases, these markets are outside of the Amazon, such as for cacao. In others, markets are more local, such as for manioc. Crop choices often depend on environmental conditions. For example, along the Trans-Amazon Highway in Altamira, Brazil, Moran et al. (2002) found that cattle ranching tended to be more prevalent in farms with poorer soils, access to water and credit, and higher ownership turnover. In contrast, the importance of permanent crops increased in farms with better soils, more family labor, and lower ownership turnover. Nonindigenous producers often incorporate traditional knowledge and crops into their systems. Indigenous knowledge is used, for example, to select the best soils available in an area (Thayn, Price, & Woods, 2011).

The age of the family also affects productive land uses (McCracken, Siqueira, Moran, & Brondizio, 2002). Initial strategies, during the establishment of a farm by young families with small children in previously forested land, favor the establishment of annual crops, which can be consumed and sold quickly. At this time, land under production expands rapidly. With time, as children become young adults, land use diversifies, including the expansion of family gardens, cattle ranching, and later of perennial crops, which are productive activities that require more time to be realized. Perennial crops also require substantial labor investment, thus reducing the rate of expansion of the area farmed (Castro et al. 2013). As families mature, land use becomes more stable. McCracken et al. (2002) and Browder (2002) estimated that between 80 % and 90 % of labor inputs in four nonindigenous agricultural areas in the Brazilian Amazon in the early to mid-1990s were done by family members. Productive activities showed some segregation by the gender and age of the farm worker. For example, young adolescents and females tend to help with domesticated animal husbandry (and household chores). Older boys increasingly work with cattle. Differences accentuate during

adulthood. For example, adult males played a larger role in the clearing and burning of forest patches to open new agricultural plots, and adult women were more involved with harvesting and food processing.

Food Technology in Africa

Richard Nnamdi Okagbue

Food processing embodies all treatments applied to foodstuffs after harvest, capture, or slaughter to prepare them for consumption or preservation. Treatments may be single or suitably combined physical, mechanical, chemical, and biological procedures which modify foodstuffs aesthetically, nutritionally, texturally, and organoleptically.

In traditional Africa, food processing is a daily domestic or village-level activity. Women constitute the main workforce and appropriate skills are acquired informally during the process of acculturation. Male professional blacksmiths, stone-cutters and wood carvers, basket makers, and others produce the grindstones, earthenware pots, pans and plates, wooden pestles, mortars and spoons, baskets, knives, calabashes, and gourds used in the processing.

In addition to familiar food plants and animal resources some uncommon products have food uses in certain areas of Africa, depending on their availability and on the prevailing culture and religion. For example, toxic castor oilseeds (*Ricinus communis*) and leaves of the toxic legume *Cassia obtusifolia* are processed into food condiments in Nigeria and Sudan, respectively. *Spirulina*, a “vegetable” microbe, is consumed in Chad, and caterpillars called mopane worms constitute human food in Zimbabwe. Other items include dog meat, cow and goat blood in parts of Nigeria, Kenya, and Zimbabwe, and gall bladder juice, hides, and skins in Sudan and Nigeria, respectively.

First-stage processing is a preliminary treatment used to release valuable seeds and fruits from heavy pods, heads, or husks. Melon pods (*Citrullus vulgaris*), breadfruit heads (*Treculia africana*), and oil palm husks (*Elaeis guineense*) are examples, and they are generally allowed to rot or soften over a period of time. The process may occur in the farm or bush to circumvent transportation and pollution problems.

Retting occurs naturally, but it is aided traditionally by hitting the structure on a hard surface or with a machete in order to rupture it. After about a week, the rotten seed-containing pulp is scooped into a basket. Loose material leaches out, leaving the seeds which are washed and sun-dried.

Sundrying precedes other steps for treating cereal heads to release grains and for shelling legumes and other fruits like the castor seed. Dried millet, sorghum, and rice heads or husks are threshed on hard ground or pounded lightly in a mortar to detach the grains; rice is invariably pounded. Mixtures of grains or seeds are winnowed with flat winnowing baskets. Then manual screening separates the food material from the chaff.

On a large-scale sun-dried pods of legumes such as the cowpea (*Vigna* sp.) are packed in jute bags, and then shelled by being beaten by sticks or trampled upon. One method of separating mixtures of seeds and chaffs is to spread them on a mat across a distance of 4–5 m. The lighter chaffs fall-off during the throwing, and denser seeds are retained on the mat.

Overall, first-stage processing eliminates bulky wastes from harvests and prepares foodstuffs for markets and for further processing. The products mostly remain inedible or unpalatable.

In second-stage processing, foodstuffs undergo textural and organoleptic modification to yield palatable products or flours and oils. Two categories of second-stage processing will be treated—those not involving fermentation and those which are fermented.

Cooking with water, frying in oil, and roasting are commonly used methods. Individual cooked items or suitable mixtures may be pounded into sticky doughs and eaten with relishes. Pounded yam is popular in West Africa, and small amounts are also used for thickening soups or relishes. Ordinary cooking suffices for preparing some cocoyam (*Colocasia esculenta*) varieties but at least one toxic variety is detoxified by prolonged boiling.

Leguminous seeds are generally cooked and consumed with their skins (testas). However, groundnuts (*Arachis hypogaea*) and the bambara nuts (*Voandzeia subterranea*) are often cooked in the pod and later extracted manually.

Smoking is rarely used for preserving plant-based unfermented foods. In contrast, sundrying is widely practiced. Raw or lightly cooked thin slices of sweet potatoes may be so preserved in Zimbabwe, but thinly-sliced cassava is cooked and washed thoroughly before sundrying, to remove the cyanide and guarantee a safe product. In the Chad Republic, mats of *Spirulina*, a microscopic alga which grows in ponds around Lake Chad, are sun-dried for use as a vegetable in local sauces.

Roasting is traditionally carried out with a burning or glowing fire and is commonly applied to tubers and plantains. Among the legumes, only groundnut seeds are roasted. Cowpea seeds are dehulled, without roasting, by first soaking them in water overnight. Placing the container on the surface of water in a deep bucket or pan makes the testas float, and they are skimmed off. Wet dehulled cowpea seeds are pounded further and ground into a slurry which is seasoned and fried in hot palm oil to form palatable balls called *akara* in Nigeria.

Many kinds of dried foodstuffs are processed into flours. In Southern and Eastern Africa, flours from grains are called meals, as in maize meal, and production begins with pounding and winnowing to remove coarse chaffs. The grains or the mortar are then moistened to prevent scattering during a second pounding. The material is then sun-dried for a few hours and finally ground on a grindstone. The finished meal is sun-dried on a mat before storage or use.

Yam and sweet potato tubers are peeled, chipped, and blanched by soaking the chips overnight in hot water before sundrying, pounding, and grinding. In processing cassava flour, chips of peeled and sun-dried tubers are ground.

Many other types of foodstuffs are processed into flour. Shelled groundnuts are roasted and ground for meat seasoning in Nigeria and as a source of butter in Zimbabwe. Various dried spices are also processed into powders.

Cooking oil is extracted from raw or cooked palm fruits and from roasted groundnut seeds. By pounding oil palm fruits in a deep mortar the oil-laden fibrous pericarps are abraded from the kernels which are sorted manually. Batches of the fibrous mass are subsequently warmed in a wide-mouthed earthenware pot to melt the oil. Then suitable portions are pressed between the palms of the hands and the oil flows into a bowl or other container.

Food processing by fermentation is widespread in Africa and various cultures have developed methods of fermenting selected food resources for different purposes. Virtually every kind of foodstuff can be fermented, and suitable processes produce heavy main course meals, condiments, and flavor enhancers, nonalcoholic and alcoholic beverages, meat substitutes, and foods for the elderly, infants, and the convalescent.

Cassava tuber is processed mainly by fermentation to detoxify it by eliminating the cyanogenic glucosides linamarin and lotaustralin and to impart desirable flavors. Important fermented products from grated material include *gari* (West Africa), *attieke* and *plakali* (Ivory Coast), and *oyoko* (Zaire).

Major products of fermenting cassava are *chikwange* (Central Africa), *ntuka* (Zaire), and

fufu (Zaire and Nigeria). The fermentations are retting processes because they soften the tubers. For *chikwange* and one form of Nigerian *fufu* the fermented pulp is mashed and sieved through a basket into a cloth bag; the solids are concentrated by pressing the water out. Meals are prepared by steaming portions of the processed material, and then kneading, boiling, and pounding into a gel. In Zaire the fermented pulp is steamed (*ntuka*), or sun-dried, milled, and cooked (*fufu*).

African cereal-based fermentations result in diverse foods and beverages which satisfy different nutritional needs. Maize (*Zea mays*), sorghum (*sorghum bicolor*), and various millets – pearl millet (*Pennisetum glaucum*) and finger millet (*Eleusine coracana*) – are the fermentation substrates and products include acidic porridges, nonalcoholic beverages, and opaque beers.

The first step in preparation of acidic nonalcoholic beverages and porridges is soaking the cereals. Subsequent sieving, sedimentation of solids, and decantation of liquor leaves a product which can be molded into various sizes for sale. They are particularly useful for infant weaning and convalescent feeding.

Examples of acidic nonalcoholic drinks are Southern African *mahewu*, Nigerian *kununzaki*, and Sudanese *hulumur*. In *mahewu* preparation, a suspension of maize meal in boiled water (1:9) is cooked and cooled. Some wheat flour is added and the drink is ready after a day's fermentation. Nigerian *kununzaki* uses flour produced by grinding grains soaked in water for 1 or 2 days. Sudanese *hulumur* is prepared by flavoring cold water with flat sheets of fermented and baked sorghum dough prepared with equal amounts of flours from malted and unmalted sorghum.

African acidic alcoholic beverages are produced from malted grains. Malting involves germination of the appropriate grain followed by malt grinding and mashing in warm water to saccharify the malt. Unmalted grain or another carbohydrate source may be added to the mash before fermentation, which may proceed naturally or by induction with a starter from a previous brew.

Clear beers are relatively rare in Africa. Nigerian *otika*, Cameroonian *amgba*, and Sudanese

assaliya are exceptions. *Talla* is an Ethiopian home-brewed beer which differs from the others in some respects. First, it is brewed with barley or wheat, hops, or spices. Secondly, it has a smokey flavor due to the addition of bread darkened by baking and use of a fermentation vessel which has been smoked by inversion over smoldering wood.

Sugary plant juices and saps and honey are the substrates for wine and spirit production. West African palm wines are produced by fermenting saps from oil palm trees (*E. guineense*) and from *Raphia* palm trees (*Raphia* spp.). In Zimbabwe sap from the ilala palm tree (*Hyphaene benguelensis*) is fermented into wine, while in Northwest Africa a wine called *lagmi* is produced from the sap of the date palm. Over-ripe bananas and plantains are also used for wine production in Southwestern Nigeria. For West African palm wines, the best known, fresh juice tapped into gourds contains up to 10 % sugar and has a neutral pH. The fermentation occurs naturally and in 24 h lowers the sugar content considerably, acidity develops, and alcohol builds up so that the wine becomes intoxicating.

Spirits are processed in Africa by distillation of fermented sugary substrates. Zimbabwean *uchema*, Nigerian *ogogoro*, and Ghanaian *ekpeteshi* are distilled from Zimbabwean ilala palm wine and from West African palm wines. Kenyan *chang'aa* and Nigerian *kai-kai* are distilled from fermented cane sugar juice. Generally the alcoholic content of African spirits ranges from 20 % to 30 %.

Food fermentations based on oilseed and leguminous seeds are sometimes called vegetable protein fermentations. West African *iru* or *dawadawa* (from locust bean), *ugba* (from oil bean), various *ogiris* (from melon, fluted pumpkin, *Telfaria occidentals*, castor bean and sesame), and Sudanese *sigda* (from sesame oilseed press cake) are fermented vegetable protein foods, and they are flavor enhancers.

Sudanese *kawal* produced by fermentations of leaves of a toxic legume *C. obtusifolia* and Nigerian *ule* are examples of African food products of leaf fermentation. *Kawal* and *ule* are flavoring materials for stews and other relishes.

Meat fermentation is uncommon in West Africa. However in Sudan virtually every part of a carcass including bones, hide, and gall bladder juice is fermented for food purposes. Fermented gall bladder juice is called *itaga*. It is prepared by adding some sorghum flour or grains to the juice which is then hung up to dry slowly. *Itaga* is pounded and used as a kind of spice for fatty meat dishes.

Fish is processed like meat, and fermentation is also uncommon. It appears to be a last resort for preserving a day's unsold catch. *Bonome* and *guedj* are fermented dried products of Ghana and Senegal, respectively. Fresh fish is allowed to undergo putrefactive fermentation in the open air for 20 h. It is then eviscerated, soaked in salty sea water, and dried in the sun for 2–4 days with or without filleting. Sudan has a variety of fermented fish products including pastes and sauces prepared from fresh water Nile fish.

Many insects, especially gregarious and seasonal types, were traditionally acceptable as food in Africa. Examples are locusts, swarming winged reproductive termites, the large cricket (*Brachytrypes*), and caterpillars of the African silkworm (*Anaphe* spp.). Traditional processing of insects included cleaning and salting, then roasting or tying in parcels and boiling. Although the practice is now restricted to isolated areas of the continent it is noteworthy that in Zimbabwe the commercial product *madora*, also called mopane worms, consists of edible caterpillars. *Madora* is available in markets or in supermarkets. The caterpillars are generally squeezed after capture to press out the digestive fluid, then salted and preserved by sundrying.

The art of fermenting milk is widespread in Africa. Cattle and camels are important dairy animals, and milk fermentation products vary widely. For example, *jben* and *ayib* are Moroccan and Ethiopian cheeses, *nono* is a Nigerian yoghurt-like product, and Zimbabwe and Sudan also have fermented milk products. African milk fermentations occur naturally with attendant souring or coagulation, the milk having usually been collected into clay or earthenware pots or animal skin bags, gourds, or calabashes. They are often churned to produce butter. Moroccan *jben*

is prepared by placing the coagulated milk (*raib*) in a cloth at room temperature and draining the whey. In Kenya various additives such as wood ash, animal blood, urine, and sometimes leafy vegetables may be added to preserve a fermented sour milk called *maziwa lala*.

Scientific Bases of Some Traditional Practices

African traditional food processing is a cultural activity which evolved independently from modern science and technology. Nevertheless valid scientific explanations can be offered for many food practices.

In many traditional fermentations, starters consisting of small amounts of previously fermented materials are introduced into new processes. Scientifically speaking, the starter contains a dense population of relevant microbes which accelerate the new process. Also, most fermentations are carried out in warm conditions, or fermentation time is prolonged in cold weather; these practices are consistent with scientific knowledge of beneficial and adverse effects of warmth and cold on the growth and activities of microbes.

Traditional food preservation with plant extracts is exemplified in the processing of Nigerian palm wine and *nono* with *nche* and *kuka*. Both preservatives inhibit spoilage microorganisms by means of chemicals: *nche* contains phenolics and alkaloids, and *kuka* contains tartarates. Again, the use of small amounts of urine, among other things, for improving the shelf life of Kenyan sour milk has been explained in the context of the lactoperoxidase system which inhibits Gram negative, catalase positive bacteria in milk. Traces of hydrogen peroxide and thiocyanate are known to be present in urine and these may exhibit antimicrobial effects together with lactoperoxidase which normally occurs in bovine milk.

Traditional food softening or flavoring with extracts from ashed monocot heads or husks is exemplified by the use of Sudanese *kambo* from sorghum, Nigerian *ngu* from palm oil husk, and

Zimbabwean products from yellow nut grass (*Cyperus esculentus*) and maize cobs. Ashing concentrates inorganic elements, and high levels of potash in the leachates influence flavor and soften foods by hydrolysis.

African traditional food processing involves diverse food resources, equipment, practices, and products. Productivity is low, and final products often lack good hygienic quality, uniform composition, and predictable shelflives.

Research efforts to modernize food-processing systems have been intensified in African institutions. Production of Southern African opaque beers and *mahewu*, Nigerian *gari*, *dawadawa*, and *poundo* yam have become industrialized, and microbiologically safe processes have been developed for production of Moroccan and Ethiopian dairy products. These developments are encouraging and continuing research efforts will probably assist future generations in preserving Africa's rich traditional food heritage.

Food Technology in China

H. T. Huang

Agriculture started in China with the domestication of rice in the middle reaches of the Yangtze Valley at about 8000 BCE. Rice was followed by millet (at about 5000 BCE), wheat and barley (1500 BCE) and soybean (1000 BCE). In the classical period (1000–200 BCE), the principal grains of the realm were millet (both panicum and setaria), rice, wheat, barley, and soybean. Much ingenuity was expended by the Chinese to develop methods for processing these crops into attractive and nutritious articles of food and drink.

The kernels of both rice and millet are relatively soft. They were steamed to produce tender, palatable granules called *fan*. Pottery steamers of great antiquity (4000–5000 BCE) have been found in the neolithic sites in Banpo near Xian in the north, and at Hemudu near Hangzhou in the Yangtze delta. It was probably the use of steaming that fortuitously led to the discovery of a

distinctive technology for the conversion of cereal grains into alcoholic drinks.

The Discovery of *Qu* (Chinese Ferment)

The fragrant, fluffy *fan* granules obtained by steaming rice grains were not only appetizing to humans, but also highly attractive as a medium for the growth of airborne fungi, such as those of the genus *Aspergillus*, *Rhizopus*, or *Mucor*. As these fungi proliferate they produce enzymes which hydrolyze the starch in the granules into fermentable sugars. Yeasts then multiply on the hydrolyzed granules and convert the sugars to alcohol. This mixed culture of fungi could be used to inoculate larger amounts of *fan* to produce an alcoholic drink, or dried and stored as a stable solid product known as *qu* (translated as *ferment*) for use in future fermentations. As we shall see, in addition to its role in alcoholic fermentations, *qu* ferment was the foundation upon which a rich array of fermented foods were later developed.

Alcoholic Drinks

The use of *qu* to make an alcoholic drink or wine called *jiu* was probably practiced in China as early as 2000 BCE. The technology for *qu* and *jiu* reached a mature level by the Han Dynasty (206 BCE–AD 220). Extensive recipes for preparing varieties of *qu* and *jiu* (as well as vinegar from it) are given in the *Qimin yaoshu* (Important Arts for the Peoples' Welfare), of AD 544. In making wine, *fan* (steamed millet or rice) was mixed with *qu* and the semisolid medium allowed to ferment until the substrate was depleted. The semisolid mash was then pressed and clarified to give the finished wine. One interesting innovation was the cumulative addition of fresh *fan* to the medium before the substrate was spent. This technique made it possible for skilled brewers in the sixth century to produce wines with alcoholic contents that were comparable or even superior to those of grape wines in the West.

During the Song Dynasty (AD 960–1280) the art of heating the wine before storage, later called pasteurization, was introduced; a red *qu* based on strains of *Monascus* sp. was developed, leading to the production of the so-called yellow or red wine. Although bronze stills were known as early as the Han, distilled spirit did not become commercial until after the Song dynasty. The fermented mash was placed directly on a grid in a boiler and the alcohol carried over by steam distillation. The result was a spirit with a strikingly rich flavor and an alcohol content of greater than 50 %.

Malt Sugar

Sprouted rice or millet, *nie*, was of equal antiquity as *qu* in China and it has been suggested that some of the earliest wines might have been made with *nie* as the saccharifying agent. But soon *qu* displaced *nie*, and the *nie*-based fermentation died out. *Nie* from wheat or barley, however, lived on as the agent for converting steamed millet or rice into malt sugar, the most important sweetener in ancient China. Although its importance declined somewhat when the refining of sugar from sugar canes was introduced from India in the Tang Dynasty (AD 618–905) malt sugar continued to be a popular treat in the Chinese diet until the present day.

Products from Wheat Flour

Since the kernels of wheat are hard, they cannot readily be made palatable by boiling and steaming. Thus, wheat was less popular than millet or rice in ancient China. However, the situation changed during the Han when mills for grinding wheat into flour or *mian* became widely available. The dough made from *mian* could be processed into a dazzling variety of delicious pastas, cakes and breads (including leavened breads). Most of these products were cooked by steaming or boiling. As a result, wheat flour soon

became the staple food in the North while rice remained the staple food in the South.

Probably the best known Chinese food processed from wheat flour is the filamentous noodle, *mian tiao*, which was first made in the second century AD. There is, however, no evidence that Marco Polo ever brought filamentous noodles from China to Italy. Filamentous pasta was already known in Italy before Marco Polo was born. It appears likely that the concept of filamentous noodles had traveled from China to Italy by transfusion along the Silk Road in the tenth to twelfth centuries.

Another important product processed from flour is wheat gluten *mian jin*, an valuable source of protein for vegetarians. It is obtained by the continuous washing of wheat dough with water. The phenomenon was first described in the *Qimin yaoshu* (AD 544), but gluten did not become a popular component of Chinese foods until the Song.

Soybean Processing

Although soybean is an excellent source of protein, it is hard to cook and difficult to digest. Three methods have been developed to process soybeans into wholesome, attractive, and nutritious products. The first is simply to allow the beans to sprout in the dark. Soybean sprouts were known before the Han as a medicament; they did not become popular as food until the Song. Since then sprouts from both soybean and mung bean have remained standard fare in the Chinese diet.

The second method is to process the beans into *doufu* (bean curd). The steps involved are: (1) soaking the beans in water overnight, (2) grinding the beans to a puree, (3) filtering the puree through cloth, (4) heating the milk to near boiling, (5) adding a coagulant, such as bittern, to the cooled milk, and (6) pressing the soft curd in a wooden frame. The procedure is depicted in a mural in a late Han tomb (second century AD), although the product did not become commercialized until the late Tang.

Since then *doufu* has been the most important vegetarian source of protein in the Chinese food system. Soymilk, however, was not accepted as a food until the eighteenth century.

The third method is to ferment the cooked beans with *qu* in a high salt medium to give a triad of relishes and condiments; they are *shi*, fermented bean relish, *jiang*, fermented bean paste, and *jiang you*, soy sauce, probably the best known processed soybean product in the West. When cooked soybeans were incubated with *qu* and salt, the product was *shi*. When they were incubated with *qu*, wheat flour and salt, the product was *jiang*. Both *shi* and *jiang* were already made on a large scale in early Han. Recipes for their preparation can be found in the *Qimin Yaoshu*. Soy sauce was simply the liquid drained from *shi* or *jiang*. It was known during the late Han, but the name *jiang you* did not come into common usage until the Song.

Much of this distinctive food technology was transmitted to Japan during the Tang and later dynasties. Thus, *qu* and *jiu* are known as *koji* and saké in Japan; *shi*, *jiang* and *jiang you* evolve into *natto*, *miso* and *shoyu*; while *doufu* remains as *tofu*. All these products have become integral parts of the food system in Japan, Korea, and Vietnam. They are now gaining acceptance in the West.

However, the best known dietary product from China is actually a drink. Tea was first prepared by steaming, crushing, and drying the leaves of *Camellia sinensis* during the Han. It became widely popular during the Tang, and was disseminated to the West in the seventeenth century. Tea and coffee are now the two major beverages consumed throughout the world.

Food Technology in Latin America

Judith Vidal

About 5,000 years BCE, native populations in the Caribbean and Latin America developed food technologies which enabled them to exploit their natural biota and become settled. By the time of the Columbian encounter, Indians had evolved unique agricultural techniques suitable for efficient food production in various terrains and climates. Their indigenous staples were cassava (*Manihot esculenta*), maize (*Zea mays*), potatoes (*Solanum tuberosum*), and yams (*Ipomea batatas*), beans, and squash supplemented by fruits and vegetables, fish, turkey, deer, dogmeat, and guinea-pigs, as well as assorted beverages and flavorants.

Food technology began with soil preparation and with the selection of seeds, roots, tubers, or cuttings. The ground was cleared through slash-and-burn and girdling, which is removing a ring of tree bark. Farmers then worked the earth into numerous knee-high mounds several feet in diameter (*montones*), collectively called *conucos*, among the stumps in irregularly shaped fields, or *milpas*, fertilized by ashes and decaying vegetation. These mounds produced less water runoff, and hence less erosion, than traditional European fields plowed in rows.

In the Caribbean, Middle America, and South America, *conucos* were planted with bitter cassava, with a vegetable triad such as maize-beans-squash, or with potatoes in the Andean highlands. In the lake regions of Mexico, floating garden islets (*chinampas*) formed of dense intertwining

roots covered with soil and plants could be paddled over the water. In the Andes, irrigated stone-walled terraces (*andenes*) allowed farming steep grades in narrow strips at higher altitudes dominated by llamas, quinoa, and potatoes, descending in ever broadening tiers to cacao, cacti, and tropical fruits at lower levels, each with its own biota, creating a diverse diet in a small vertical space. Where the parched soil of valleys was unyielding, natives removed the earth's surface in expanses as large as an acre to form *hoyas* (pits) which reached natural moisture and permitted cultivation.

Indians learned to cultivate strains of indigenous flora by taking cuttings, by planting tubers, or by carefully selecting seeds which they planted individually in small holes poked by a planting stick called a *macana* in the Caribbean and a *taclla* in the Andes. These methods produced more uniform quality than European broadcast seeding and resulted in higher caloric production per acre than Old World counterparts of wheat, rice, millet, and barley.

The bitter cassava (also known as *yuca brava*, manioc, mandioca, tapioca, and *farinha*) roots from 2 to 6 in. in diameter were dug up, peeled, and grated. The wet pulp was then stuffed into long mesh baskets and hung from a beam which allowed for twisting to express the poisonous prussic acid. When the toxic juice was removed, the pulp was forced through basket sieves or pounded, and the resulting flour was spread in flat three-foot cakes on hot stone grills or dried and stored for later use. The poisonous liquid was safe to drink after boiling. From Colombia southward down the Pacific coast of South America, a nontoxic sweet cassava was similarly processed and often made into preserves.

The true staff of life for most of Latin America was maize. This Indian corn occurred in hundreds of varieties and colors. Indigenous cultures hybridized the silky tassels by hand to breed the most desired traits. Some kernels were so hard they had to be soaked or chewed before boiling gruels. Women pounded grilled kernels with stones to produce a flour meal for tortillas or other dishes. Dried grain was also stored indefinitely in elevated, aerated storage silos.

Indians of the upper Andes invented freeze-dried potatoes by alternately exposing the tubers to night frost and sunshine. Within a few days all the water was removed, leaving a potato preserve called *chuñu* which could be further whitened or reconstituted by steeping in water. Lightweight and easily transported, the *chuñu* could be preserved indefinitely like cassava or maize. There were over 3,000 types of potatoes, sweet potatoes, ocas, and other tubers. Bean and seed pulses were also important foods throughout Latin America. They too were dried for preservation if not cooked immediately.

In addition to drying, there were several other technologies for preserving foods. These included salting, pickling, fermenting, toasting, and ensiling. Fish was salted as was meat cut into strips. Brine solutions and lime mixtures were also used. Vegetables and fruits were pickled in a variety of herbal vinaigrettes. Fruit and vegetable juices were fermented and distilled into alcoholic beverages which were also used as preserving agents.

Among native beverages, cacao (*Theobroma cacao*) was the most lucrative exchange commodity in New Spain and parts of Peru. Cacao trees were grown by Indians in orchards shaded by large "mother" trees. When the large red pods ripened, they were picked, and hundreds of bitter-tasting seeds were removed by chewing the luscious fruit. The sun-dried seeds were used as money or ground and roasted for a bitter brew restricted to nobles and ceremonial rites. Under Spanish colonization, the chocolate beverage gained widespread popularity in Mesoamerica.

In the Pampas, another stimulating beverage came from a native tea known as *maté*, steeped in boiling water like East Indian varieties. When coffee was introduced to tropical Latin America, it was prepared much like cacao and was widely consumed. All three of these nonalcoholic beverages grew in popularity with the increasing availability of sugar and vanilla which replaced pepper as the preferred seasoning.

In addition to flavor enhancement, many herbs and spices were used to preserve foods and to add medicinal benefits. Seaweed supplemented natural salt sources in Andean diets to protect natives

from goiter. Tropical fruits added vitamin C. Cinnamon, cloves, and capsicum peppers preserved as well as flavored foods. Sarsaparilla was a refreshing beverage which soothed gastrointestinal ailments. Another vegetable product, *guayacán* treated syphilis while *cuasi*, a valuable insecticide, also eased fever symptoms. The most important treatment for malaria came from quinine or *chinchona* which remains a viable cure as well as a popular tonic water.

Alcoholic beverages were consumed in moderation before conquest. In Mexico, the agave or maguey was fermented and distilled into pulque, mezeal, and tequila. Maize was fermented into a beer-like beverage called *chicha* which was popular throughout Middle America and the Andes. *Chicha* could also be fermented from a variety of fruits. Other alcoholic beverages came from fermentation of potatoes, cassava, and tropical fruits such as pineapples and bananas. These were sometimes mixed into brandy called *aguardiente*. None of these beverages became popular in Europe, but rum – fermented from cane sugar – became commercially successful throughout North America and Europe.

Prior to European contact, indigenous populations had few meat sources and no beasts of burden other than the llama and the dog. With the introduction of horses, cattle, oxen, sheep, swine, goats, mules, and donkeys, they gained transportation, meat, and power to plow, haul, and operate mills. They also received protein-rich meat and dairy supplements to their diets. By-products from domesticated and feral herds included fibers, leather, tallow, bones, and horns.

Among the food cultigens brought to the New World, the grape-grain-olive culture remained heavily European. Sugarcane and coffee, however, dominated enormous regions where native labor consumed the stimulants while working plantations. Both commodities were labor-intensive requiring hand planting and harvesting. Sugar works (*trapiches* or *engenhos*) used human, animal, or water power for the crushing mills which released the sugary syrup. Slaves operated a train of boiling vats to purify and clarify the liquid for evaporation. The resulting muscovado sugar was 96 % pure and was

packaged in cones or loaves for shipment to European refineries. Hand-picked coffee beans were spread on patios to dry before roasting and shipping.

Many of the technologies used by indigenous populations are practiced today throughout rural areas of Latin America. Scientists are studying their techniques and lore for insights into environmental protection, expanded food production, and medicinal applications. Global dietary diversity has been accompanied by language enrichment as a result of food exchange. As a result of Latin American food technology, words such as barbecue, olla, mezquite, cassava, tapioca, quinine, banana, palm, tomato, etc. have joined the alimentary menu.

The Indians practiced ecological efficiency and perspicacity unrivaled by the colonial powers who imposed a wheat-wine-oil-meat agriculture in lands more suited to manioc, maize, and potatoes. None the less, dietary diversity has been enhanced throughout the world as a result of native Latin American technologies which first unlocked the secrets of preparing and preserving exotic New World foods which have become staples for subsistence.

Food Technology in the Pacific Islands

Richard Beyer
Suva, Fiji

The range, variety and sophistication of food preserving and commercialisation activities throughout the Pacific Island Nations (PINs) are as varied as the climate, agricultural framework and culture. The techniques so necessary for basic survival have been the foundation of food preservation but the practises have been refined and expanded since European arrival. Countries such as Fiji and the Marshall Islands are now home to highly sophisticated food processing operations sponsored by multinational companies that have been attracted by tax incentives and relatively low wage rates. The ethos of food processing and food exploitation has infiltrated wider communities as the international food standards defined by Codex Alimentarius have been adopted by *inter alia* Vanuatu, Samoa, Tonga, the Cook Islands and Fiji. Countries such as Kiribati and the Federated States of Micronesia remain at the other end of the spectrum but the importance of maintaining food quality has been strengthened by the mandatory conformance to the hazard analysis and critical control points (HACCP) system of quality maintenance for economically important fish exports to the US and EU markets (Beyer, 2000, 2003a, 2003b, 2003c). The welfare of the people of the Pacific nations is nevertheless highly dependent on subsistence farming and traditional preserving techniques (Laban & Swain, 1999) particularly of fish and starchy staples – cassava, taro, plantain, yam, breadfruit and sweet potato (Bradbury, 1987).

Traditional Preserving Techniques

Historically, processing has been confined to practises that will preserve foods to reduce waste and to extend availability, particularly for foods with very short seasons (Atkinson, 1990;

Beyer, 2001; Greenwell, 1947; Kordylas, 1991; Kwatia, 1986a, 1986b, 1988; Parker, 1967; Root Crops Development Newsletter, 1982; Root Crops Processing, 1993). Traditionally, foods have been preserved using techniques that exploit environmental factors (Atchley & Cox, 1985; Atkinson). Sun drying has been used extensively as a means of extending shelf life because of the high ambient temperatures prevalent in the tropics. The process is benign – fish, occasionally pork, vegetables and fruits are merely sliced and laid on racks to dry. If prevailing conditions permit, the foods reach a final moisture content that will inhibit mould growth and the products are edible although not always appetising. In many cases vegetables turn brown, mould may grow before the drying process is completed – or occasionally later if the dried food reabsorbs water as a result of increases in relative humidity during storage. Other products may bleach and become tough.

A number of readily available chemicals have been used to stabilise foods. Salt obtained by sun-evaporation of seawater has been smeared onto root crops to prevent bacterial and mould growth. In other cases, the vegetables are dipped in seawater prior to drying and the salt concentrates during the drying process. Sun-dried lime segments and evaporated lime juice have been used to increase the shelf lives of some root crops and bananas – the vitamin C and the low pH (citric acid) both act as preservatives. Dusting with wood fire ash has been used to prolong the shelf life of breadfruit and yams. In this case, the high pH is hostile to moulds and other bacteria.

Many of these traditional preserving techniques continue to be appropriate for the preservation of root crops in the rural areas. Political upheaval in countries throughout the region has retarded economic progress, and economic empowerment has proceeded at rates below aspirations. Traditional food preservation techniques remain relevant but the end products enjoy declining popularity – particularly among the young. Some of these traditional products continue to appeal to older members of the community and to older expatriates now living in Australia, New Zealand, Canada and the USA.

As a natural evolution, there are isolated instances where those products have formed the basis of export industries. Where markets have persisted for traditionally preserved foods, processes have been standardised with conformity in manufacturing techniques.

Nutritional surveys around the region however indicate that the consumption of traditional foods is decreasing. Such industries as the garment industry and tourism have provided increasing employment for women. As their time for food preparation has become eroded, they have become less tolerant of traditional foods such as yams, cassava and taro in favour of more convenient (often cheaper and lighter) alternatives such as rice and flavoured noodles (FNFC, 1997, 2000; Food Security: The New Millennium, 1999; Hodge et al., 1997; Paterson & Crossland, 1999).

Travel, tourism urban drift television and other lifestyle changes have transformed food choices in the PINs. Although much of the food is imported, local entrepreneurs have copied and modified a number of these imports and form the basis of a wide range of small scale processing operations (Beyer, 2001).

Conventional Preserving Techniques

Dehydrated Products

The cost of removing moisture from foods rises exponentially as the moisture content drops (Brennan, 1994). Thus it is in the processors' interest to remove only that proportion of water that impinges on the keeping quality of the finished product. Not only are processing costs reduced to a minimum but also the product retains some water, which adds to the weight. Unfortunately, intermediate moisture foods (a_w values between 0.35 and 0.6) deteriorate unless they are protected with preservatives, humectants or antioxidants. Only at very low moisture contents (a_w values <0.3) is deterioration kept to a minimum. The exceptions are non-hydrolytic reactions, which usually take place in fats and oils. Rancidity will continue in low moisture foods and may occur even faster than in moist foods because the reactants are very concentrated

by the lack of moisture. It is important therefore that low moisture foods are protected with antioxidants. Antioxidants such as butylated-hydroxy-toluene (BHT) and butylated-hydroxy-anisole (BHA) and even ascorbic acid can be used.

Recent innovations in dehydration and drying are directed towards reducing the relative humidity of the air used for drying by removing the water vapour rather increasing its temperature. So-called heat pump dryers pass heated air, which has previously been used for drying, over cooling coils. The water vapour in the drying air condenses on the cooling coils and thus the relative humidity is reduced. The same air is used repeatedly on this drying cycle. The low temperatures used in this technique cause less oxidative damage and food dried by this means is usually much higher quality. The heat pump dryers are used in some PINs for products where ultimate retail price advantage justifies the capital expenditure and the running costs, which in turn depends on the cost of electricity.

Throughout the PINs some success has been achieved in early trials using secondary air dryers. Secondary air dryers rely on drying an intermediary component – commonly coconut husk using wood-fired drying kilns. Ambient air is then circulated around the pre-dried coconut husk, which removes the water vapour. This reduces relative humidity of the air that is then passed over the food. The food – particularly in the latter stages of drying – is not subjected to high temperatures and therefore suffers less deterioration.

Modern processing techniques have been applied to a number of products including dried cassava dalo, fruit slices and some thinly sliced fish. The sliced product is immersed in a solution containing 150 ppm of sodium metabisulphite (or 200 ppm ascorbic acid). For vegetables they use 1–3 % w/v of sodium chloride (soy sauce is used sometimes especially with fish). The slices are then dried on racks in a heat pump drier. The maximum outlet temperature of the drying air is 55 °C, which is sufficiently low to prevent browning due to caramellisation of the simple sugars. The relative humidity of the outlet air is 55 %, F

which gives a value for water activity of a_w of 0.55. Some sulphite is lost during the later stages of drying as sulphur dioxide.

These products are then shelf stable and do not brown on storage. Residual polyphenolase activity is inhibited by sulphite or ascorbic acid.

Dried granules from the starchy staples have also been developed as the raw material for extrusion. Extrusion technology has been applied to corn and rice starch and combinations of them. During extrusion, granules are forced at high pressure through a heated die. At the very high temperatures and pressures, the starch molecules align in the direction of shear and superheated water boils off rapidly as the pressure on the mass is released. This opens out the matrix to give the familiar honeycomb texture, which is a characteristic of puffed snack foods. Cassava granules in particular perform very well using this technology and preliminary trials have indicated that cassava is a likely candidate for future research and development (R&D) programmes.

Canning

Dalo, cassava, breadfruit and some local vegetables (e.g. *duruka*) and fruits have been canned and exported for some 12 years. The very high temperatures used in canning are responsible for significant damage to the texture and flavour of fruits and vegetables. The products have very soft textures and the heating regimen results in warmed over flavours characteristics of Amadori compounds. These quality characteristics are thus significantly different from fresh items. The market is somewhat resistant to such quality features and sales are consistent but small. Similar products canned in coconut milk are marginally better and sales figures are higher but coconut milk supplies are inconsistent.

Fruit and vegetables processed in retortable pouches (polypropylene/aluminium/foil/nylon/polyethylene laminate) have better quality characteristics because the heat penetrates to the centre of the pouch faster, but the technology is not readily available in the Pacific region (overpressure retort).

Conventionally canned fish (tuna) is the largest single item of canned food produced and

exported from the Pacific region with very large factories in Fiji, American Samoa and the Marshall Islands and smaller factories located in Tonga and Manu Samoa.

An alternative technique (Beyer, 1998) is a multiple pasteurisation technique. Foods are packed in polyethylene/nylon bags and vacuum-sealed in such a layout that the products are not touching and that heat can reach every food surface. They are then immersed in boiling water for sufficient time for the heat to penetrate through the bags so that the surfaces of the foods reach at least 80 °C for 15 s. The pouches are then cooled using cold water to prevent over cooking.

In low acid foods, this is sufficient to destroy the vegetative cells of bacteria but not the spores of thermophilic organisms. However the heat shock is sufficient to encourage germination of the spores. These are then destroyed by pasteurising again 24 h later by immersion in the boiling water bath for enough time for the temperature at the surface of the vegetable to reach 80 °C for 15 s. As an extra insurance measure, the package is heated in the same way on a third day. This is sufficient to destroy surface bacteria. With carefully handled vegetables, the deep tissue will be sterile. Thus this technique should result in pack sterility. In the event that the packs are still not sterile – which would be manifest by blowing – the product can be reheated for a fourth time since the heat penetrates to the same depth each time and damage to the product is still confined to the outer surface. The technique means that relatively little heat is applied to the surface of the vegetable and the damaging effects of the heat penetrate only a short distance into the tissue. The vegetable has the appearance texture and taste of fresh vegetables.

Freezing

In the short period of 30 months preceding May 2000, an export industry in free-flow frozen root crops was established, which peaked in February of 2000. At its maximum volume, 66 tonnes/month of frozen cassava were being exported to Australia (Beyer, 2000). Much smaller volumes were destined for New Zealand. Trial shipments were also sent to Japan, but large-scale exports

were not possible because of cyanide levels that exceed Japanese standards. An unexpected demand has arisen for frozen root crops however, and production level is well below market demand.

Fry Drying

There is now a plethora of small fried snack root crop and plantain producers throughout the PINs. Products are becoming commonplace and some are emerging as export products. Entrepreneurs are encouraged to use these products as a basis for increasing market depth and width through product development programmes described as more appropriate technology and products. By mixing into dough there are many opportunities to:

- Extend using other ingredients
- Improve acceptability by adding flavours
- Improve nutritional value by adding other ingredients such as carrot and tomato (vitamin A)
- Add improvers to extend shelf life
- Produce more consistent products

The cooking medium can have a significant bearing on the acceptability of the final product. Commonly soya bean oil is used, since it is the cheapest of the frying oils. The viscosity of oils is temperature-dependent. Oil temperature should be high as the product is removed. At high temperature, the oil is mobile and drains from the product easily. At low temperature, the oil adheres to the product, thereby increasing costs (oil is commonly very expensive in the PINs). Fried snack foods with high oil contents are more prone to rancidity during storage, they are nutritionally less desirable and the mouth-feel is poor.

Oils used for cooking should therefore be heated to temperatures a little below the smoke point and relatively small quantities of product added to it, to prevent excessive cooling. Used oil should never be topped up with fresh oil since rancidity is autocatalytic – the products of rancidity catalyse the onset of rancidity. Thus used oil should be stored and allowed to settle. It may be washed with water and the (more dense) water

layer drained. It can then be shaken with dried calcium chloride that can be subsequently removed from the oil by filtering (and re-dried for repeated use). The used oil pooled in such a way can be used for several processes after it would normally have been discarded.

Rancidity is accelerated by ultraviolet light, some divalent metals such as copper, (cast) iron and zinc and oxygen. Product keeping quality can thus be enhanced by high quality processing equipment fabricated from stainless steel and by using packaging material (usually incorporating foil) which is opaque to ultraviolet light and which prevents the transmission of oxygen. Vacuum packing improves keeping quality even further.

An antioxidant – an agent that captures free radicals – will also protect the product. Oils are frequently sold with antioxidant added. The antioxidants of choice are BHA or BHT. Unfortunately, these antioxidants are volatile and are lost after only two or three frying cycles so that they do not carry over into the final product. This assists the oil manufacturer because oil must be replaced more frequently, but the snack food is not protected to the same degree. A preferred antioxidant is tertiary butyl-hydroxy-quinone (TBHQ), which is not volatile and which carries over to the product for longer period. This affords antioxidant protection after the product is packaged and will assist in prolonging shelf life.

Current Food Activity

Commercial factors have been responsible for shaping the current status of food technology in the Pacific region. Unlike more developed regions of the world however, the strong cultural foundations have enriched the industry with the modernisation of traditional food preserving methods. Liberalisation of migration policies has resulted in alarming population movements from the island nations to Australia, New Zealand and the USA, however these immigrants have become nuclei markets for exported traditional foods. More than that, they have become ambassadors in the role of introducing new foods to their newfound fellow consumers.

Hence the region has a spectrum of food-related activity not only in the degree of sophistication of the technology but also in the demands of the markets.

Forestry in India

Deepa Pande

One of the earliest civilizations of the Indian subcontinent was that of the Indus Valley (third or fourth millennium BCE). It was here that cedar (*Cedrus deodara*) and rosewood (*Dalbergia latifolia*) used for coffins was found. A wooden mortar of ber (*Zizyphus mauritiana*) for pounding grain and charred timber of *Acacia* spp., *Albizia* spp., teak (*Tectona grandis*), haldu (*Adina cardifolia*), and *Soyamida febrifuge* were also found. This shows that Neolithic people not only made extensive use of wood, but also understood its particular characteristics for different purposes. This concept today is known as forest utilization.

Evidence of tree worship during the Indus Valley civilization is exhibited by various seals of the Harappan culture which depict the pipal (*Ficus*) and weeping willow (*Salix*) trees. Trees were an essential and integral part of the life support system and considered existing agencies of the creator of God.

Just as forests played an important part in Vedic India, tree worship was also practiced by the Aryans. Because of the human dependence on trees, they were venerated and protected by religious injunctions; their planting was encouraged by a promise of eternal bliss in future life. *R̥g v̄ eḍa* and *Aṭhar v̄ aveḍa*, basic texts of the Vedic period, contain several hymns praising and endowing trees, plants, and vegetation with various divine qualities, highlighting their medicinal significance, and enunciating the policy of conservation or sustainable management. Various *Upaniṣads*, a later group of philosophical treatises that explain the theology of Hinduism, like *Bṛhaḍāruṇyaka*, *Chāndogya*, *Chulikā*, and *Muṇḍakopniṣaḍa*, conclude that trees had life akin to human life. *Maṭsyapurāṇa* and *Varāhapurāṇa* describe the benevolence of trees along with the rituals of tree planting. *Skandapurāṇa* contains a long list of trees which should not be cut except for the purpose of *yajnas* (holy rituals). Whereas planting of trees led to heavenly comforts (*Agnipurāṇa*) indiscreet felling of trees meant torture in hell.

Vedas also contain valuable information about various species of birds. In *R̥g v̄ eḍa* for instance there is a mention of *Garuda* (eagle), *Mayūra* (pea fowl) along with various Himalayan pheasants, partridges, and other species of birds. Surprisingly *R̥g v̄ eḍa* also mentions not only anatomical details of some common birds, but also details about their staple food. For example *Vartika* (partridges) are said to have well-developed bills, legs, and rounded wings; their food consisted of grain, grass, weed, seed, tender shoots, insects, and even white ants. These kindled the sparks of wildlife management during the later period of civilization.

Great saints and sages who understood these texts, passed on their knowledge and wisdom to their disciples. Such education was given in the *Gurukuls* (schools) which were located in the forests. The students lived in the forests and continued their studies. Thus a sense of tolerance and coexistence with various forms of plant and animal life was infused in early childhood. This *Aranya* (forest) culture provided early exposure to nature study and ecology, as well as the policy

of development without destruction in current parlance. Forest and environment consciousness was thus ingrained into the educational system from the very onset.

Even epics and religious texts written later on describe the protective role of trees and their unlimited usefulness. *Rāmāyaṇa* and *Mahābhārata* describe the rich biodiversity and multiplicity of flora and fauna. In *Bhagwaṭgītā* Lord Krishna compared himself to the *Aśvaṭha* (figus) tree in order to emphasize the importance of trees.

Other religions of that time also mentioned the importance of forests and forestry. According to Lord Buddha it was the obligation of every good Buddhist to plant and nurture at least one tree every 5 years.

Moving along chronologically we find that forest management practices were well documented during the reign of Chandra Gupta Maurya (321–296 BCE). Reliable historical documents, such as the *Indika* of the Greek ambassador Magasthenese, the *Arṭhaśāstra* of Kautilya and the *Mudrārākṣasa* of Viśākhaḍaṭṭa vividly depict various aspects of forestry and wildlife. Kautilya's *Arṭhaśāstra*, recognized as the pioneer work in economics in India, indicates the existence of a regular Forest Department headed by *Kūpyādhakṣa* with definite duties and responsibilities for various officers of the department. Some of the important duties of *Kūpyādhakṣa* were to increase the productivity of forests, classification, price fixation, and disposal of various types of forest produce, raising block plantations of important species (e.g., sandalwood), pasture development in saline-alkaline waste lands, and joint management of forests with people dependent on forests.

Forests were legally classified into three main classes: reserved forests, forests donated to eminent Brahmins, and forests for public use. They were classified into six categories on the basis of crown density, luxuriance, growth, and origin. Planted forests were called *Upvana*.

Forest and game laws were stringent and draconian, containing corporal punishment. The death sentence was envisaged for poaching of elephants. Awards were provided to a person who collected elephant tusks from dead elephants

and deposited them with government officials. Kautilya's treatise also dealt at great length not only with the use of various trees and shrubs, but also with the specific use of various parts. For example it indicated that flowers of *Palās*, *Kusuma*, and saffron are used as dyes, *Munja* and *Love* grass are used for making ropes, and fruits of *Aonla*, *Harara*, and *Bahera* are used as medicines.

Emperor Aśoka adopted and improved these practices. Plantation of fruit-bearing shade trees for the benefit of travelers and common people was started on an ambitious scale. Aśoka was the founder of *Abhyāranya*, the *sanctum sanctorum* of wildlife, now known as National Parks and sanctuaries. Aśoka's edicts at Sarnath Varanasi bear ample testimony to the above.

Forestry flourished during the Gupta period (320–800). *Śukranīti*, a well-known work of that time, throws light on the improvements in forest management practices. Seeds of "Social Forestry" were sown during this era. *Śukranīti* dwells on the concept of village forests, choice of species, afforestation and maintenance techniques, fertilization procedures, irrigation schedules, and measures to increase flowering and fruiting in trees. Names of various multipurpose trees such as *Kaḍamba*, *Sīśama*, *Peepal*, *Mango*, *Nīm*, *Coconut*, and *Imlī* are listed in this policy document for planting near villages. Incidentally many of these are also listed in the latest ICRAF (International Council for Research in Agroforestry, in Kenya) booklets. This shows the worth of these ancient publications.

It is thus clear that in ancient India trees were the best friend of people in a hostile environment. They were held sacred, worshipped, and studied in great detail for service to humanity. Forestry practices evolved gradually, in a scientific and rational manner, and are important even today, although in the modern parlance new names have been coined for them.

Forestry in Japan

Conrad Totman

Forestry may be defined as "the science and art of forming, caring for, or cultivating forests." Another definition is "the science, the art and practice of managing and using for human benefit the natural resources that occur on and in association with forest lands" (The former definition appears in *Webster's New Collegiate Dictionary* (Springfield, Massachusetts: G. & C. Merriam

Co., 1956); the latter in Grant W. Sharpe, et al. *Introduction to Forestry*. 4th ed. New York: McGraw Hill, 1976. 187, quoting the Society of American Foresters). The former, dictionary definition, leaves unidentified the interests to be served by this “science or art.” The latter, autecological definition, with its explicitly human beneficiary, was propounded by the Society of American Foresters around 1970. It fitted nicely the Japanese approach to woodland for centuries down to about 1980. Since then, however, socioeconomic changes have undermined the established rationale of forest policy, permitting advocates of environmental protection to call for a richer synecological understanding of forestry’s proper purpose.

Factors Shaping Japanese Forestry

In Japan, as elsewhere, forestry has been profoundly shaped by its geographical and social contexts.

By global standards the Japanese archipelago is extraordinarily youthful and mountainous. Mostly formed in the past 15 million years, it is characterized by elaborate dendritic systems of acutely upthrust ridges that are covered with thin, immature soils and incised by narrow valleys down which course fast-running streams that eventually debouch onto slender alluvial plains, most of which front the surrounding seas.

Because of the way continental and oceanic weather patterns interact in the northwestern Pacific region, Japan experiences pronounced seasonal differences and a relatively moist climate during most of the year. And its length from north to south assures it substantial variation in mean temperatures, which range from subtropical in the far south to subarctic in the far north. In consequence woodland vegetation is lush everywhere. But it varies from a thin strip of evergreen broadleaf forest along the southern littoral through woodlands of mixed deciduous broadleaf and evergreen firs (which cover most of the realm) to coniferous boreal forest in far northern regions and at high elevations.

Before the introduction of fully fledged horticultural practices some 2,500 years ago, these richly forested islands supported a very modest population of foragers. Once agriculture was introduced, however, the population grew rapidly, and over the course of two millennia cultivators opened much of the archipelago’s lowland to cultivation or other human use. In the process, forest was eliminated from most lowlands and lower slopes of hilly terrain, an outcome reflected in the language. Forest of any substantial dimension is called *sanrin*, literally “mountain-forest,” while the more basic terms for “woods,” *mori* and *hayashi*, which lack reference to mountains, are ordinarily used when talking about small residual groves of trees or parcels of brushwood that have chanced to survive on or near lowland.

Nevertheless, because Japan is so extensively and acutely mountainous, even today about 70 % of it still sustains woodland. Part of this is plantation stands and part mixed, natural growth, some subject to management, some not.

Within this physical context, forestry in Japan has moved, as it has elsewhere, through two major phases, from a long era of exploitation forestry to a shorter era of regenerative forestry. The latter runs from the seventeenth century to the present but can be examined in terms of preindustrial and industrial-age segments.

Exploitation Forestry

For millennia residents of the islands utilized their woodland primarily for fuel and food. With the development of agriculture, however, food came more and more from arable land, and the receding forest provided, instead, water and fertilizer materials to grow the food, fodder for beasts of burden, construction timber for buildings and gadgetry, and fuel for cooking and various industrial tasks, notably metallurgy and kiln work.

During the seventh and eighth centuries CE, political consolidation gave Japan grand capital cities that housed a ruling elite of unprecedented power and cultural pretension. They adopted new architectural styles and construction techniques

that led to a major increase in the consumption of both timber and fuel wood (see Timber-Handling Technology in Japan). These developments led in central Japan to overcutting that created serious problems – flooding and drought, forest fire, wood and fuel shortages, and intensified competition for control of surviving woodland. On the other hand, because the Japanese did not maintain herds of goats and sheep for milk, meat, or wool, Japan's landscape was spared the devastation they have wrought elsewhere.

In the outcome, although the problems caused by overcutting did gradually become more widespread as Japan's population grew and towns proliferated, it was not until the seventeenth century that broadly effective patterns of remediation began to be devised and applied. They emerged then because a sharp increase in wood cutting and another surge in land clearance were having severe downstream consequences during an era when society was well enough organized so that purposeful woodland regulation and management could not only be needed or advocated, but in fact be devised and implemented in a sustained manner.

Regenerative Forestry

Regenerative forestry can be examined in diverse ways. One approach discusses “negative” policies designed to prevent or contain unauthorized exploitation and “positive” policies designed to foster more, better, or different types of forest performance. An overlapping formulation speaks of “protection forestry,” which is designed to protect the woodland itself and other areas and affairs vulnerable to damage caused by unwise forest use, and “production forestry,” designed to enhance the quality or quantity of woodland yield.

In terms of the former approach, local instances of negative forest policy date from the eighth century, when rulers tried to restrict cutting in select locations. Negative policy became visible again during the 1300s–1400s, when some villages in central Japan began regulating the use of their communal woodland, and during the

1500s, when some regional barons (*daimyō*) tried to protect valued groves and stands from unauthorized harvest.

It was from the 1660s onward, however, that the hegemonial Tokugawa shogunal regime (ruled 1600–1868), the 250-odd daimyo, and villages all across the realm began drafting and enforcing, in woodland within their jurisdiction, regulations to control who might do what, where, when, how, with what tools, and how much yield. Those initiatives developed into a wondrously variegated system of multiple-use rights that allowed diverse people to extract diverse goods from designated parcels of woodland throughout Japan.

Regarding timber specifically – which was of particular concern to the rulers – shogun and daimyo not only regulated the harvest in forests they administered as domanial land, but also began stipulating that no good-quality tree of desirable species was to be injured or felled, save with official permission. And that prohibition applied to all formal categories of land, whether of village, fane, or household, even to include trees standing on a villager's house lot.

To enforce their proliferating rules, shogun, daimyo, and village headmen deployed forest wardens, guards, and patrols to catch rule-breakers. They established fines and other punishments, and they developed and applied adjudication procedures for handling those charged with violation of forest law.

These negative policies, together with vigorous programs of riparian management and repair, did gradually achieve major goals of protection forestry, reducing appreciably the extent of erosion and downstream silting, flooding, and damage. But in terms of production forestry, the rate of harvesting on accessible hillsides was so great that negative policies alone failed to sustain fuel, fodder, fertilizer, and timber supplies at the level of demand. And on numerous lower hillsides, especially those facing the agricultural lowlands of central Japan, overuse gradually destroyed vegetation, creating more and more barren hills and ridges known as *hageyama* or “bald mountains.”

Under these circumstances positive policies designed to promote plantation stands, nurture

mixed forests, and revitalize *hageyama* began to be advocated by government officials, village leaders, and Confucian scholars of the “practical learning” (*jitsugaku*) orientation. During the eighteenth century, moreover, land-use arrangements were gradually modified, creating forms of rental forestry that assured users long-term control of select parcels and their yield. These modifications encouraged landlords, entrepreneurial lumbermen, villages, and daimyo to invest time and wealth in programs of woodland planting and nurturing, confident that in due time they or their successors would recoup the investment.

As interest in reforestation spread, the body of silvicultural writings grew apace, enriched by the testimony of practicing tree farmers. It provided detail – mostly practical and biologically sound – on the selection, collection, and preservation of seeds and cuttings, on the preparation and use of seedbeds, on the transport and transplantation of seedlings and rooted cuttings, on the suppression of competing vegetation, on pest control, on restocking failed shoots, and on nurturing the growing stand to produce wood (or other) products with the desired qualities. Writers also offered advice on the use of rotation-cutting schemes, on techniques of stand valuation and harvest, and on wood processing and storage.

By the decades around 1800, and on into the nineteenth century, both plantation stands and managed forests of mixed, multiaged new growth were becoming valued sources of timber throughout Japan. They eased the overall timber shortage that had spawned regenerative forestry in the first place. And while *hageyama* were still common and much woodland was still poorly stocked, the humanly fostered forest did, by enhancing Japan’s volume of standing timber, help equip the realm to handle the traumatic decades that lay just ahead.

Industrial-Age Forestry

During the 1850s–1860s the global wave of early industrial European imperialism finally reached Japan, where it overwhelmed the decentralized

Tokugawa regime in 1868. The new Meiji government saw its primary task as mobilizing sufficient power not only to stay in office, but also to stop further foreign inroads and to repudiate the concessions previously made. Within this new and radically changed context, there were some strong continuities in forestry thought and practice, but the changes seem more noteworthy.

Both protection and production agendas continued to be clearly visible, the balance between them shifting with the ebb and flow of woodland condition and global context. And much of the existing silvicultural knowhow and procedure continued to be applied in planting, nurturing, and harvesting projects.

Even in terms of silvicultural content, however, change gradually occurred. One factor spurring it was new technology, particularly that of the harvest, which placed great new demands on woodland and its handlers (see Timber-Handling Technology in Japan). More strikingly, the practice of forestry became far more systematized. Whereas Tokugawa-era forestry had utilized precedents from China, Meiji leaders took their cues from current practice in industrial societies, Germany most notably. Starting in the 1870s, a number of Japanese studied forestry there and upon their return helped forestry officials develop new policies and launch new programs. By 1883 that government effort had created a school of forestry, a forestry experiment station, a professional association of foresters, and a research bulletin.

In following decades those trends continued: regional forestry associations proliferated, more and more professional meetings were held, technical matters were debated, and new techniques were tried. Students and officials continued going to Germany to study forestry, and German works on the subject were translated into Japanese. New journals appeared; more experiment stations and forestry training programs were established, and the body of trained foresters and published research findings grew apace.

From the outset Meiji leaders had claimed domainial woodland as government forest, and by the 1890s they had created a Forest Agency and subordinate bureaucracy to manage their

newly unified system of national forests, which encompassed more than half of all wooded acreage. Later, authorities also developed programs of guidance and assistance for owners, mostly small-scale, of the remaining woodland.

On government woodland foresters developed both overall management plans and local operational plans. Revealing ever more sophistication as decades passed, the overall plans spelled out policies for afforestation, aftercare, harvesting, and the handling of road construction and other forest-engineering projects. They dealt with the technical tasks of mensuration and the fiscal, spatial, and material requirements of projects. They detailed personnel needs, particulars of organizational structure and of research and operations facilities, and estimates of income and expenditures.

Nor was the planning merely a bureaucratic exercise. Research and training in scientific methods did improve. Forest mensuration, one of the world's more arcane arts, made striking advances. The relatively simple task of measuring acreage gained accuracy as more surveyors were trained and deployed and as surveyor's levels and the techniques of triangulation were introduced and mastered. The much more difficult tasks of estimating stumpage volume and predicting timber yield advanced more slowly as "eyeballing" gave way to increasingly refined techniques of estimation, including the use of sample plots. And foresters began developing yield tables for particular species in select localities.

In their research work, professional foresters also undertook studies of specimen growth, soil acidity and its effects, factors affecting seed-germination rates, and other projects designed to improve forest productivity. They also imported and experimented with seed and seedlings of valued foreign species. By the 1920s they were becoming familiar with the concepts of forest succession and continuous forest, and they were beginning to look more skeptically at such recently touted practices as rotation clearcutting, fixed yield rates, and even-aged monocultures.

Behind – and clearly influencing – this story of forestry's development was a less tidy tale of ups and downs in the actual woodland condition. During the decades from about 1870 to 1900, Japan's forests were ravaged by a combination of pushes and pulls that spurred villagers, entrepreneurs, and government loggers to hack down stands, clear land for cultivation, and otherwise misuse it in ways that produced flooding, erosion, and downstream damage. Decades of later-Tokugawa forest recovery were undone. But from about 1900 into the 1930s governments at all levels and private landholders responded by pursuing remedial policies to control flooding, restock forests, and maximize their rate of sustainable production. By the 1930s, these efforts were yielding results all across the realm: reforestation was being pursued widely, flooding problems had abated, *hageyama* were being revitalized, and the volume of standing timber was gradually increasing.

Then, however, during 1937–1950, industrial-age warfare and its consequences undid the gains, stripping the realm of much woodland cover and again producing widespread and destructive erosion, flooding, and damage. That situation precipitated yet another effort at forest rehabilitation, by far the greatest in Japanese history. During the 1950s–1960s countrywide planting restabilized the hillsides, adding thousands of hectares to the country's hand-planted woodland. By 1980 Japan was again a green archipelago, lushly forested from far north to far south. And today about 40 % of its forest acreage is in plantation stands, most of it trees 30–50 years old.

That outcome has not, however, proven an unqualified triumph. By 1960 the Japanese lumber industry was becoming enmeshed in the global timber trade, and imported logs and other wood products undersold nearly all the domestic competition. In consequence, by 1970 logging had lost most of its profitability, and reforestation and aftercare had become uneconomic, an investment that carried no promise of eventual return. By then, too, shifts to chemical fertilizers, fossil fuel, and motorized machinery had destroyed the

F

Forestry in Japan, Fig. 1 Near Ueda City in Central Japan, March, 1963. By 1950 many of Japan's forests had been stripped of timber, but in following years the hillsides were replanted. By 1980 most of these hillsides

again sported rich young timber stands. In foreground terraced rice fields give way to dry fields which ascend the hillsides as far as gradient allows (Photograph by the author)

markets for green fertilizer, fuel wood, and fodder for draft animals. Woodland had become useless. It was merely pretty scenery.

Since the early 1970s, therefore, tree planting, stand maintenance, and logging work have all been in sharp and sustained decline. Indeed, logging activity today yields only about a quarter of the peak output of ca. 1940–1960. Instead, intermontane regions depopulate as young people in particular leave to find employment elsewhere. And both plantations and mixed forests simply stand and age, increasingly subject to windthrow and snow breakage and gradually losing their potential economic value (Fig. 1).

Because of these developments, Japanese forestry has recently been facing a crisis of purpose. Government committees and other groups have continually, and especially during the 1990s, drafted and redrafted rules and guidelines,

categorizing and recategorizing woodland, giving more emphasis to protection forestry, and formulating purpose one way and another. But at present the basic problem of an uneconomic resource persists, and no coherent and effective policy for addressing it has emerged either within the Forest Agency itself or within government or society more broadly.

So, from a human-centered autecological perspective, Japan's forest affairs currently seem to be in utter disarray. From a broader synecological perspective, of course, it would seem a golden opportunity to encourage the final evacuation of depopulated intermontane regions and their revitalization as more richly diverse biomes. Perhaps even wolves could be reintroduced to manage the population of wild ungulates – deer, wild boar, and serow – that now constitute a widespread nuisance to people. And at the same time, one could pursue at little social cost the gradual,

managed restoration of many plantation stands to wildlife-friendly mixed forest.

However, in Japan, as elsewhere, the former perspective – the human-centered autecological assumption that forests exist to serve human purposes and that they do so best when subject to enlightened human management – continues to prevail despite the small voices that fret about biodiversity, species endangerment, and extinctions. And it seems likely that as the twenty-first century advances, global wood scarcities will revive Japan's plantation-based timber industry and revalidate the production-forest priority before a synecological perspective gains effective voice.

G

Gaitian

Christopher Cullen
Needham Research Institute, Cambridge, UK

Gaitian is the Chinese name for a scheme of cosmography, i.e., a description of the overall layout of heaven and earth. The term may be interpreted as “umbrella [-like] heaven.”

The classical description of the *gaitian* view is found in the ► [Zhoubi suanjing](#) (Mathematical Manual of Zhoubi), dating from around the beginning of the Christian era. It seems likely however that it is a systematization of what was the common view of the shape of the heavens at least as early as 250 BCE. Heaven and earth are more or less flat and parallel planes, although they may sometimes be described as gently curved like the cross section of an umbrella. Earth is stationary, while heaven rotates once daily about an imaginary vertical axis through the north celestial pole, carrying the heavenly bodies with it. Day and night occur because this rotation carries the sun beyond the range of the observer’s sight and back again. The rising and setting heavenly bodies are an optical illusion. In winter the sun is further away from the celestial pole than in summer, and is hence more distant from the observer and lower in his sky.

The *Zhoubi suanjing* gives the height of heaven above earth as 80,000 li. The Chinese observer is said to be 103,000 li from the subpolar point, while the greatest and least radii of the sun’s daily orbit round the pole are 119,000 li (summer solstice) and 238,000 li (winter solstice). The scheme gives a fairly good qualitative explanation of obvious phenomena, including the 6-month alternation of day and night at the earth’s north pole. By the second century AD it becomes clear that mathematical astronomers preferred not to think in *gaitian* terms, but were using the so-called ► [huntian](#) (continuous heaven) scheme.

Gan De

Huang Yi-Long

As one of the earliest astronomers in China, Gan De, in the fourth century BCE, made many observations of the heavenly bodies, especially Jupiter, which was then called *Suixing* (the year-star). He wrote two books: *Suixing Jing* (Treatise on Jupiter) and *Tianwen Xingzhan* (Astrological Prognostications). Unfortunately these books were lost long ago, and only some quotations from them are extant in the *Kaiyuan Zhanjing* (The Kaiyuan Treatise on Astrology), compiled between AD 718 and 726.

In the *Kaiyuan Zhanjing*, Gan De is quoted as saying: “Jupiter was very large and bright. Apparently, there was a small reddish star appended to its side. This is called ‘an alliance’.” Included in the quotation were a date and rough coordinates, both in the ancient Chinese system.

Zezong, of the Institute for the History of Natural Sciences in the Academia Sinica, Beijing, claims that this record is evidence of the earliest discovery of the brightest moon of Jupiter, Ganymede, in the summer of 365 BCE.

Although Ganymede’s magnitude of 4.6 is somewhat brighter than that of the naked eye’s limit, Jupiter is 760 times brighter and located less than 5.9 arcmin away from this moon. Only people possessing eyes of extraordinary power would be able to see the satellite. Could Gan De have been one of these extraordinary people? We will never know.

Some people claim, on the basis of experiments, that under good observational conditions, the normal naked eye can determine Jupiter and its brighter satellites, especially Ganymede. However, Gan De’s reference to the reddish color continues to be mystifying, because Ganymede is too faint for its color to be perceived with the naked eye.

Gardens in Ancient Egypt

Angela Torpey

Formerly at Centre for Lifelong Learning
University of Warwick, Coventry, UK
Formerly at University of Manchester,
Manchester, UK

Even in damp climates and in a well-dug garden, archaeology can yield significant results (Currie, 2005, Fig. 2, p. 3). Drawings, paintings, and plants provide further information. Our knowledge of ancient Egyptian gardens comes from tomb reliefs, models, ostraca (often bits of broken pottery although some ostraca such as the figured ostraca discovered in the Great Pit at Deir el-Medina at Thebes can also be bits of limestone which was also readily available from the surrounding hillside), texts, and the archaeology itself. Although tomb scenes come from the tombs of the nobility, every house would have at least a little herb plot, often close by in the cultivation, and often a single tree in a pot in the courtyard of the house (Fig. 1).

In ancient Egypt, gardens were surrounded by mud-brick walls, with a gate facing the river. Walls were practical, to protect the garden from more unwelcome wildlife. From the Middle Kingdom, two simple models of gardens have come down to us from the tomb of the chancellor Meketre at Thebes. In front of the little portico of the house is a formal garden. In the center, copper

Gardens in Ancient Egypt, Fig. 1 A modern courtyard garden on the west bank at Thebes (Photograph © the author)

represents a rectangular pool. On each side are little trees representing the sycamore fig.

Trees would have been an important part of any Egyptian garden, a source of shade for people and the garden, for fruit, and for protection. In the tomb of Ineni, four registers show the tomb owner's house and garden. Among the trees listed are date and dom palms, sycamore fig, pomegranate (introduced into Egypt in the New Kingdom), persea, tamarisk, and olive trees. Planted just inside the enclosure wall, tall trees would also serve as a windbreak against spring and autumn gales which sweep across the Western Desert and could be very destructive. A relief from the tomb of Nebamun, now in the British Museum, also shows two rows of date and dom or gingerbread palm trees and sycamore fig trees on three sides of the garden just inside the enclosure wall (Fig. 2).

Trees also lined the causeways of the “mansions of millions of years,” the so-called mortuary temples known best from the West Bank at Luxor. Three rows of seven trees, sycamore and tamarisk, lined the causeway of Nebhepetre Mentuhotep II's “mansion of millions of years” at Deir el-Bahri. Trees and flowers lined the causeway of the Temple of Amun-Re at Karnak. Several different kinds of trees are shown in the Great Temple of the Aten at Amarna (Fig. 3).

Trees were planted in a specially dug hole, filled with fertile Nile silt. In the tomb of Meryre

Gardens in Ancient Egypt, Fig. 2 One of two simple models of the garden of the “Overseer of the Six Great Law Courts”, “Chief Steward” and “Overseer of the Seal” Meketre. (Photograph © Alison Bone)

I at Amarna, trees are shown in individual planting holes with a rim raised to hold the precious water. By a quirk of art style, the rim seems to represent the akhet sign, the “horizon” of the sun

Gardens in Ancient Egypt, Fig. 3 Persea, sycomore fig, cornflowers, mandrake and poppies fill the garden of Ipuy. In the water are blue and white lotus. (de Garis Davies, 1927, Plate XXVIII)

deity, the Aten. Other trees are shown on what appears to be a raised mound, symbolic of the island of creation. Unbaked bricks are shown protecting trees in the Dynasty 18 tomb of Mosi (Wilkinson, 1998, p. 169).

A series of images at Queen Hatshepsut's temple at Deir el-Bahri shows the transportation of incense trees. Ancient Egypt had two words for incense, *snTr* which grows wild in Egypt's Eastern and Western Deserts and *antyu* which came from Punt which the ancient Egyptians called "God's Land" and was an important trading center further south down the Red Sea. Texts and reliefs from the queen's successors also show trees brought from Punt. This may suggest it was not possible to cultivate *antyu* successfully in Egypt (Dixon, 1969).

It is possible that vegetables and grapevines could have been grown under trees. This would certainly be a good use of space but would have been detrimental to the trees and the vines (Eyre, 1994, p. 62). Grapevines, which may not have been indigenous to Egypt, were known and cultivated from at least the Old Kingdom. The grapevine ceiling in the Dynasty 18 tomb of Sennefer on the west bank at Thebes is a testimony to the importance of grapevines, both for their fruit and their shade (Fig. 4).

Watering was both labor-intensive and time-consuming. A scene in the Dynasty 5 mastaba tomb of Mereruka shows servants watering lettuce. Water is carefully poured from pots carried on yokes across the shoulders of the servants. Single pots would also be used to water small plots. It is also possible that individual plants or plants planted in close proximity could have been drip-fed by pottery jars buried or part-buried under the surface (Springuel, 2006, p. 58). Note too "a broken pot found at the base of a tree-planting hole" at Amarna (Leach, 1982, p. 9).

The shaduf, a simple device to lift water from a canal or well, was not known until Dynasty 18. A relief, though damaged, from the tomb of Meryre I at Amarna shows part of a shaduf. Three scenes in the Dynasty 18 tomb of Neferhotep show gardeners directing water from a shaduf to fruit and orchard trees (Butzer, 1976, Fig. 8, p. 44). Rainfall, sometimes heavy, would be a welcome resource (Fig. 5).

In the hot climate of Egypt, evaporation was a major problem. Two shallow lakes were discovered at the Maru-Aten at Amarna. Unfortunately, the original excavators did not investigate how the lakes were filled (Barry Kemp, 2014 personal communication). One possibility is that a well was dug close to the enclosure wall. Despite its

Gardens in Ancient Egypt, Fig. 4 Grapevines form a cool arbour in the palace gardens of Queen Tey (de Garis Davies, 1948, Plate XIX)

proximity to the river, a number of wells are known from estate gardens. Stone conduits too are known directing water from a well to a pottery workshop (Eyre, 1994, p. 64, n. 44).

It seems, however, that the “lake” in the southern enclosure was not excavated; the shallow depression seen on the ground gave the impression of a shallow lake (Kemp, personal communication). The lake could have been a well. It is also possible each lake was originally excavated deep enough to fill naturally from the water table, the usual way of ensuring a constant supply of water to the sacred lakes of temples. Linear mounds beside the Maru-Aten, much like Birket Habu on the west bank at Thebes but smaller, would certainly suggest the lakes were excavated to some depth.

It is possible too that lotus and papyrus would have grown in the temple’s sacred lakes. This would have helped conserve water by reducing evaporation. In Papyrus Harris I, Ramesses III proclaims: “I dug a lake before it [the Ramesses III temple at Medinet Habu on the west bank at Thebes], flooded with Nun [water], planted with

trees and vegetation like the Delta.” Lotus and papyrus were symbolic. Papyrus was sacred to Hathor, “lady of the west”; the lotus was sacred to the sun deity Re. Tomb scenes always show garden pools with ducks and their offspring, fish, and blue lotus. The symbolism is of birth and new life. Lotus and papyrus would have filled two T-shaped basins in either side of the Hatshepsut temple causeway at Deir el-Bahri.

Water features, whether the sacred lakes within temple enclosure walls, T-shaped basins, or small rectangular pools in private gardens, were clearly important. In the Maru-Aten at Amarna, interlocking T-shaped basins were originally called “fish ponds” by the archaeologists. Fish could certainly have been kept in each pool, but almost certainly, the pools served a dual purpose, the practical storage of water to water the surrounding gardens and just as importantly with a symbolic meaning. T-shaped basins were also found in front of the little chapels of the Workmen’s Village. At Karnak, in the left-side corner of the back wall of the Hypostyle Hall, the king is shown before a T-shaped basin.

Gardens in Ancient Egypt, Fig. 5 One of the earliest representations of a shaduf. Note steps leading down into the pool or well. The author has seen trees and shrubs

growing happily in the sacred lake at Denderah, reaching subsoil water. The tomb of Meryre I el Amarna (Photograph courtesy of Barry Kemp)

Unusually, in the tomb of Meryre II at Amarna, the garden of the tomb owner is shown with a T-shaped pool. Clearly the T shape is important. The symbolism however is much more difficult to know. The author's personal choice is that the T shape is linked to the bark of the sun deity Re (but see Bowmann, 1991, pp. 102–114).

A rectangular pool at the center of the garden would have been surrounded by an herbaceous border. Ancient Egyptian herbaceous gardens were filled with scent and color. Flowers discovered in the tomb of Tutankhamun include leaves and flowers of cornflower, mandrake, poppy, mayweed, wild celery, persea, blue and white lotus, olive, willow, papyrus and reed mace, and the bright red berries of *Withania* nightshade (Hepper, 1990). Daisy-like faience inlay discovered at Amarna is almost certainly the white

flowers of mayweed. Rose petals are known from Hawara dating to the third century BC. Herbs would include the fragrant white flowers of myrrh and the feathery leaves and yellow flowers of dill. Very possibly, at least some of these flowers originally grew wild along the edge of the Sahara and had drifted into the gardens. Fertilizer would be Nile silt and pigeon dung. Some large gardens would be terraced (Fig. 6).

Weeding would have been labor-intensive. Ancient Egyptian hoes would only scratch the surface. Deep-rooted weeds would remain as stubborn as dandelions in grass today.

Temple gardens would have been both practical and symbolic. A relief in the south wall of the sanctuary at Queen Hatshepsut's temple at Deir el-Bahri shows a rectangular garden with formal

Gardens in Ancient Egypt, Fig. 6 One-meter-wide garden plots discovered at Kom el-Nana – el-Amarna (Photograph © Amarna Project)

Gardens in Ancient Egypt, Fig. 7 A date palm growing on the riverbank (Photograph © Ann Keane)

beds surrounded by the sacred persea. In between the persea are lettuces, sacred to the deity Min. Four pools are close by Naville (1906), plate CXLII). Single trees and small flower beds were planted in the courtyards of nobles' tombs at Thebes. Little chapel gardens are also known from the Workmen's Village at Amarna (Stevens & Clapham, 2014) (Fig. 7).

Temple gardens were important both for floral bouquets and for floral and vegetable offerings to the deity. Formal bouquets are known best from New Kingdom tomb scenes at Thebes. A small formal bouquet could comprise blue water lily flowers surrounded by buds, poppy, cornflowers, and, at the top, the fruit of *Mimusops* (persea). Bouquets were hand-tied to papyrus stalks. *Convolvulus*, wound around the papyrus stalks, may represent new birth. An ostrakon discovered at

Deir el-Medina shows either the *convolvulus* or white bryony entwined around a birthing bower. "Stick" bouquets discovered in the tomb of Tutankhamun were simply persea and olive branches. A text from Papyrus Harris I states Ramesses III gave 19,150 large lettuce and flower bouquets to the temple of Amun in just under 3 years (Manniche, 1989/1993, p. 24). This was just a small part of the numbers of bouquets and wreaths offered to the major state deities. Bouquets too were presented to high officials. In a scene in the tomb of the Dynasty 19 official Thay, the tomb owner offers a large formal bouquet to his wife. A similar scene is in the Dynasty 18 Theban tomb of Mosi (Wilkinson, 1998, pp. 168f).

Ancient Egyptian gardens would have been spectacular: the fragrance of herbs and flowers, the cool breeze through the gardens, and the gentle sound of ducks splash in the water. The gardens were clearly a place to show wealth and status for this life and for eternity.

Gardens in Japan

Wybe Kuitert

Graduate School of Environmental Studies,
Seoul National University, Seol, South Korea

The Early Centuries

Before a clearly defined native garden art appears in Japan's history somewhere in the eighth century, evidence is found of activities in the field of landscape design. It is mainly through archeology that these early centuries speak to us. At Jo-nokoshi (Mie prefecture) a set of rocks was unearthed that stand upright in a rather naturalistic manner. This group had been put up along three narrow well heads lined with shingles that flow together to feed a small stream. The arrangement has been dated between the end of the fourth and middle of the fifth century. The setting vaguely resembles a manner of handling rocks and shingles seen in a few gardens of the seventh and eighth centuries. One can only guess about the meaning these arrangements would have had for the ones who made it or ordered it to be made (Nara National Research Institute for Cultural Properties & Agency for Cultural Affairs, 2009) (Fig. 1).

Skill in engineering in this early history can be seen in bold burial mounds of advanced design, surrounded by moats. Some square ponds lined with rocks were found, as were quite a few artistic works in carved stone made to have some liquid flow (Asuka Shiryōkan, 1986). These were probably used for rituals involving rice wine or water for purification; similar artifacts are known from the continent. A well-known record, dated 612, speaks of a man who came from Paekche, a Korean kingdom; he built a garden arrangement and made a Chinese style bridge in the garden of the emperor. His name was Michi-no-ko Takumi in the Japanese reading of the Chinese characters of his name (Sakamoto et al., 1965). It underlines how the early history of landscape design in Japan followed the models of the continent.

Gardens in Japan, Fig. 1 Survey drawing of the excavated rocks and shingles at Jo-no-koshi (From Nara National Research Institute for Cultural Properties and Agency for Cultural Affairs (2009), p. 15)

At the mid-seventh-century palace site of Fujiwara-kyō, remains of a winding garden pond have been found. At a slightly later site, parts of an extensive pond garden were unearthed (Higashikage, 2013). The pond had rather heavy embankments in piled-up rock, an island and a fountain-like feature. Most likely it had been part of the seventh-century imperial Asuka palace of the emperor Tenmu (r. 673–686). Though only partly excavated, and much smaller, this garden arrangement resembles in all its details the seventh-century pond garden Anap-ji in Korea.

The Nara Period (710–784)

Nara was founded as an imperial city in 710 AD; it was planned after Chinese geometrical schemes with streets running in a grid pattern. The imperial palace held a central position in the northern part of the city. It is known from scarce records that there were several gardens. None of these remain, but two extensive gardens were discovered and redone after detailed excavation and research.

Southeast of the main palace compound, a detached palace, Tō-in, was constructed in the

early eighth century. The garden of Tō-in, or the East Palace Garden, is one of the gardens mentioned in contemporary records. Extensive archeological surveying gave a wealth of added information. The original pond bottom was paved with large flat stones. Like the Asuka pond, the heavy embankment of the East Palace Garden follows a design of simple curves, again similar to the Korean example. Interestingly, the garden had been rebuilt later in the same century, after a covering of the earlier design with soil. The second, younger pond was paved with much smaller pebbles, and the embankment runs in softer, more expressive curves. Rather than embankments, this second pond was contained with shores or beaches covered with smaller stones, the shingles found on Japan's seashore. Here and there at small peninsulas, rock groups suggested weather-beaten sea cliffs in miniature. A group of rather big and craggy stones is set as a decoration in the shore opposite the remains of a hall, traced from remains of foundation pillars. It is this second phase of the East Palace Garden that shows a clear departure from the continental style and the introduction of clearly native landscape motifs; the typical shingle beaches and

rocky promontories of Japan's natural seacoast would continue to inspire garden designers for centuries to come. The East Palace Garden has been reconstructed on top of the archeological remains. Buildings, bridge, and planting were remade in a hypothetical reconstruction of what could be guessed from what was found in the soil. For redoing the garden, the second phase with its supposedly more native expression was chosen as a point of departure (Kuitert, 1991; Nara National Research Institute for Cultural Properties & Agency for Cultural Affairs, 2009). It was opened to the public in 2004.

A second garden recovered from eighth-century Nara is known as the Palace Site Garden (*Kyūseki teien*) or after its address in the old city of Nara, *Sakyō sanjō nibo kyūseki teien*. The site was probably a private retreat of some courtly family or the emperor himself. It is in walking distance from the East Palace Garden (Tō-in). The most distinctive feature of this garden is a double S-curved, winding stream bed. The bottom of this water feature was paved with fist-sized stones in the old continental manner, but decorative rock groups at protruding curves and beaches covered with pebbles are completely in the native naturalistic manner. Drawing from a natural river, this winding stream has its water running from north to south. It is generally accepted that the garden was used for the so-called winding stream banquet: guests were sitting along the stream, writing poetry. A poem had to be finished before a cup of wine set on a float would reach the poet. This festivity became famous after the Chinese calligrapher Wang Xizhi (303–379) invited 41 men for a winding stream banquet on the third day of the third month in 353. Poetry written on the occasion was compiled in the *Records of the Orchid Pavilion*, a Chinese literary classic, well known in eighth-century Japan. The Palace Site Garden will also have been used for similar winding stream banquets. The rockwork excavated was in such perfect condition that it was decided to reconstruct the garden with most of the original stones. Remains of two sets of wooden boxes were found, set among the stones of the pond bottom; these were probably planting boxes for irises.

A banquet hall was reconstructed departing from the remains of pillar foundations found. As plant material for the Nara garden reconstructions, the Chinese plum (*Prunus mume*) and Japanese pine (*Pinus thunbergii*) are used among other plants (Kuitert, 1991; Nara National Research Institute for Cultural Properties & Agency for Cultural Affairs, 2009) (Fig. 2).

The Heian Period (794–1185)

In 794 the city of Heiankyō, now Kyoto, was founded as a new capital in a plain surrounded on three sides by hills. The city would remain the most prosperous cultural center for many centuries to come. The site for the new city was well chosen and blessed with a lot of pure water and natural springs, giving great advantage for the household and for garden building. Indeed, natural ponds and streams were used in large palatial gardens. In some cases dams were built to contain more spacious garden ponds. At the back and in between the palace buildings, sand was spread out in small court gardens, and a little stream ran among flowers, shrubs, and bamboo planted as decoration. The old glory is perceived in garden remains in Kyoto such as the one at Shinsen-en or at Saga-in, a place now known as the temple Daikaku-ji. At other places, excavations again revealed garden details. Rocks arranged to make a waterfall were found in some sites. These are never high, as gardens were made in the plain.

The noblemen of the capital built their palaces in a peculiar architectural style. After the name of the main hall, the *shinden*, it is called the “shinden style” or *shindenzukuri*. Being planned together with the buildings, the garden developed into a typical *shindenzukuri* garden style as well. Of course, each garden was different, but some characteristics can be defined. Seen from the main hall, white sand was spread in the front part of the garden; beyond it, one found a large pond that could have one or more islands. An arched and a level bridge connected islands and shores. Along the edge of the pond, one could find pebble beaches or standing rocks arranged to suggest a weather-beaten sea cliff. The typical

Gardens in Japan, Fig. 2 Banquet hall reconstructed at the eighth-century rock arrangements of the winding stream at the Palace Site Garden in Nara (Photo by author 29 October 2010)

garden stream mostly ran from the northeastern corner through the garden, often passing under the corridors connecting palace buildings, then among some low garden mounds, before emptying into the pond, usually in the southern half of the garden. Low hills at the back of the garden provided a background on the southern side (Kuitert, 2002, 2007; Mori, 1945). Inner city estates had their gardens fenced in, but fences were low always allowing for views to the hills surrounding the city on the east, north, and west (Motonaka, 1994).

But times were changing, and the twelfth century found the nobles in an unstable political situation. To counter the increasingly pessimistic worldview that prevailed, they built themselves large temples, with gardens referred to as paradise style, or Pure Land (Jōdō) gardens (Mori, Muraoka, Asano et al., 1980). Such gardens meant to reconstruct the Buddhist paradise of Amida in this world and have a temple hall with an image of Amida as a central element. Yorimichi Fujiwara in Uji, for instance, reconstructed his palace and modeled it as a temple named Byōdō-in, set in a large landscape site. Without any fence or bordering

structures, the temple buildings were scattered over the area, one pavilion jutting out over the Uji River. The still extant Amida-dō Hall, now known as the Phoenix Hall, is shown on the Japanese 10 yen coin. After an archaeological survey, medieval repairs were removed, and the original pebbled beach in front of the Hall was repaired in recent years. The shallow slope of this beach indicates how buildings were placed sensitively within the wider river plain landscape, without any forceful, large-scale engineering (Fig. 3).

These early centuries of landscape design in Japan take the continuity of natural landscape as a fundamental quality of garden beauty. This is typical of court noble gardens of palaces and of the temples in the paradise style. Other still extant gardens of the paradise style are in Hiraizumi, Iwate Prefecture, or the Shiramizu-Amida-dō in Fukushima Prefecture, and Enjō-ji and Jōruri-ji close to Nara. Many elements of the palace style remained to be used in these temple gardens as well; ponds and islands are typical. The garden stream of the temple Mōtsu-ji in Hiraizumi is extensive and resembles garden streams as represented in paintings of the period. Around

Gardens in Japan,

Fig. 3 The shallow pebble beach suggests a river gravel bar on which the Phoenix Hall of Byōdō-in was built (Photo by author 24 August 2011)

this time a nobleman wrote a well-developed manual on garden theory – the eleventh-century *Sakuteiki* (Hayakawa, 1973; Hisatsune, 1979; Kuitert, 1998; Mori, 1986; Takei, 1995; Takei & Keane, 2001; Tanaka, 1990; Vieillard Baron, 1997). It set the tradition for centuries to come. The manual stresses the workings of a poetic understanding of nature that is basic to garden making as it attaches importance to a thorough understanding of the topography of the site. Nameless workers, supervised by noblemen, built gardens in this period; a class of gardening priests soon followed (Kuitert, 2002).

The Kamakura Period (1185–1334)

Although a shogun's government of military men was set up in Kamakura, the center of culture remained Heiankyō (modern Kyoto), and all through the Kamakura Period garden art remained under strong influence from the earlier style. Temple gardens built by order of military men followed the pattern of the Paradise style. For instance, Yorimasa Minamoto, after suppressing Hiraizumi in 1189 where he had seen its Paradise temples, was greatly impressed by their magnificence. He started building Yofuku-ji in Kamakura in the same year, and in 1192 the ceremonial services for inaugurating the new buildings were performed. At present on the

designated historic site, the remnants of this garden can be seen (Fukuda, 2011).

Residential gardens of the military class did not escape the influences from the palaces of grander men, but the scale was smaller, and as the meaning as a space for ceremony was also less apparent, more attention was paid to practical use. Also, with a garden space becoming smaller, it became rather a place to look at and enjoy by admiring than a place to enter. Gardens therefore were rather a visual thing in their perceptions and were meant to entertain or impress visitors and guests. Starting from the thirteenth century, garden culture came to receive Chinese influence again, this time through visiting priests. High-ranking priests of the Chinese Song dynasty, like Rankei Dōryū (1213–1278) or Issan Ichinei (1244–1317), given with the Japanese pronunciation of their names, were influential cultural leaders of Japan. Many landscape paintings of the Song and Yuan dynasties were imported as gifts and brought a new vision of an imaginary landscape. The Chinese vision of landscape is still profoundly felt in the artistic composition of rocks arranged for garden waterfalls. For example, at Tenryū-ji and the Golden Pavilion, these rock arrangements probably date to this early period when Chinese priests were around, and the artistic expression of a steep gorge-like valley might very well have been brought in by them (Kuitert, 2002) (Fig. 4).

Gardens in Japan, Fig. 4 Rocks are arranged to suggest a Chinese style landscape painting in Tenryū-ji (From Kuitert (2002), p. 78)

The Muromachi Period (1334–1573)

The new ruling class of military men finally replaced the cultural supremacy of noblemen in Kyoto. Their general, the shogun, would gain control over most parts of the country.

The influence of Chinese culture on garden art was now backed up with a growing trade with China on an unprecedented scale, making a taste for Chinese goods the great fashion. Shogun Yoshimitsu and his palace – of which at present only the Golden Pavilion remains – naturally formed the center of this Chinese fashion. His court was affected by the Chinese mood as can be recognized in the architecture of the Pavilion. The garden is most functional through the pond at which the Pavilion sits. What makes it different from earlier ponds is that there is a large number of small islands that with their pine trees and rocks are reminiscent of the islets off the coast

of Japan. This engineering made for a peculiar view from the Pavilion where important rocks on the islands are in full view; these were once owned by regional leaders now loyal to Yoshimitsu but had been donated or confiscated for the garden (Fig. 5).

The Chinese influence in the fourteenth and fifteenth century shows in the adding of a great variety of pavilions, bridges, roofed corridors, and two- or three-storied buildings to the spacious pond gardens of earlier times. In gardens like at the Golden Pavilion, or Saihō-ji in Kyoto, most, if not all buildings, have disappeared. But the temple Eihō-ji in Tajimi (Gifu prefecture), founded at the end of the Kamakura period, is a typical example where many structures still remain. The garden takes full profit from the dramatic topography of a sharp bend in a natural valley. A small gazebo sits on a sharp, craggy outcrop. Though much smaller in scale, it echoes the continental Daoist love of dramatic rocky landscapes. Garden architecture from these days is adorned with Chinese literary titles that rely on classic literature. Later, in the days of shogun Yoshimasa around 1500, the fashionable and gorgeous Chinese taste came to an end. Growing power and influence of priests and townspeople mingling with the military rulers led to a vision where much importance was attached to sociable meetings and manners. As guests were to be received and entertained, now also by the less wealthy, smaller gardens with a more subdued and intellectual expression came up. It led to a new scenic garden style, at present referred to as “dry landscape” (*karesansui*). However, in those days it was called *kazan*, or *kasenzui*, meaning “imaginary landscape” (Kuitert, 2002; Toyama, 1934). The style strives for an abstraction of landscape by careful placing of rocks. In miniature these can be realistic and suggestive of mountains and waterfalls, while soil left bare expressed water. Sometimes this was strewn with decorative sand. The coarse, white gravel seen today is mostly a later addition. The dry landscape garden is simple in execution and cheap, making it popular for adorning the main hall of small family temples, which as a consequence, also led to an increasing need

Gardens in Japan, Fig. 5 The pond in front of the Golden Pavilion is dotted with islands decorated with conspicuous rocks (Photo by author 10 December 2009)

for intellectualism and stories attached to it. This allowed for quite abstract placing of just a few rocks that still would be called an imaginary landscape. The textbook examples of the style are now Daisen-in the Daitoku-ji monastery (Kuitert, 2013) and the garden in front of the main hall of the temple Ryōan-ji, although the latter garden was rebuilt in the late eighteenth century (Fig. 6).

Among the so-called riverside people (*kawaramono*) living at the very bottom of the social ladder, skilled gardeners called “landscaping riverside people” (*senzui-kawaramono*) became a group of professional gardeners. They become known by name in the records at the end of the Muromachi period (Kuitert, 2002). Gardeners living in and around the temple Ninna-ji have left us a detailed handwritten manual on gardening technique (*Sansui narabini yakeizu*) dating from the 1460s (Egami, 1966, 1967; Slawson, 1987).

The Momoyama Period (1573–1603)

The Momoyama period is a period of transition and sudden wealth after the country’s unification. Gardens at the expansive mansions of the powerful military leaders were in gorgeous

Gardens in Japan, Fig. 6 The imaginary landscape is seen from the room as if it is a Chinese landscape painting (From Sekiguchi (1991), p. 50)

splendor, often employing the ostentatious sago palm tree that was the great fashion of the day. One may visit the garden at the large Reading Hall of the Nishi-Hongan-ji temple in Kyoto,

was aligned with tea pavilions and tea huts or other kinds of garden architecture. Garden mounds, pebble beaches, bridges, stone lanterns, and washing basins were installed to produce scenery that changed with almost every step. This tendency to decorate the garden with numerous details became typical of the later Edo period garden developed by the *daimyo* or governors of the provinces.

These *daimyo* were obliged to live in Edo, currently Tokyo, for 6 months every year. They had their official residences in the city; some were many hectares large. The other half of the year they lived in their own home province where they constructed their gardens in the same manner. *Daimyo* challenged each other all over the country, and above all in Edo, to have the finest of all gardens; it meant that the cultural hegemony of Kyoto gardening came to an end. *Daimyo* gardens first of all served for receiving guests with banquets or to enjoy other garden pleasures, but they also signified the birth of a new garden aesthetic. The scale was large and evoked a concern for scenery; thus, a more bucolic sense is seen in miniature landscapes reproduced. Some gardens have mini Mount Fujis; others have small tea plantations or rice fields which helped in times of economic scarcity. All over the country *daimyo* left us with many good examples. In Tokyo, there are Kōrakuen, Rikugi-en, Shiba-Rikyū, and Hama-Rikyū. In Okayama one may visit Kōrakuen; Takamatsu has its Ritsurin-en, Hiroshima Shukkei-en, Mitō Kairaku-en, or Hikone the Genkyū-en garden (Kuitert, forthcoming; Shirahata, 1994, 1997).

In the course of time, well-to-do citizens also came to possess a garden, and gardening became more popular. Garden books were published and widely read, spreading a stylized mannerism that classified “the” garden in two styles each in three levels of elaboration. The thing to have was, for instance, an “elaborate hillock style garden,” or an “abbreviated flat garden” as these were shown in the picture books (Akisato, 1828; Hishikawa, 1680; Kitamura, 1735). Gardeners became professional specialists, organizing themselves in houses that would pass on the trade for

generations. Propagating and breeding of novel garden plants reached a level matching the modern garden center or even above that when it came to the varieties of ornamental plants (Hida, 2009; Hirano, 2006; Kuitert, forthcoming; Ogisu & Kashioka, 1997). Many of the once prized garden varieties of plants from the Edo period have now become extinct (Fig. 8).

Gardens of the Later Nineteenth and Twentieth Centuries

After the 1860s “the West” was brought to many facets and aspects of Japan’s society, but this did not readily reach the garden. Several western-style gardens were built in Tokyo, often with lawns, winding paths, and a lookout on a hill; an extant and successful example is Shinjuku Gyōen. But in face of Japan’s century-old tradition, these were isolated experiments, at least in the beginning (Kuitert, forthcoming; Ozawa, 1890).

Little by little though, new ideas began to inspire the top end of the garden trade. Among some captains of industry or powerful politicians, the cramped world of the picture book garden was considered obsolete, and a new taste was required, giving room for a more liberal naturalism. Some of these men, like Aritomo Yamagata (1838–1922), had taste for gardening, not in the least because they moved their place of residence often; in a lifetime they developed several estates with different gardeners in different natural landscapes (Yagasaki, 1996). In the course of the 1890s, great progress was made in Kyoto at Murin-an, a garden commissioned by Yamagata and finished by gardener Jihei Ogawa (1860–1933). The garden had meadows of wild flowers set among a pastoral landscape of meandering streams, set before a background of natural hills outside the garden. The meadows and trees and shrubs reflected Japan’s agricultural landscape around Tokyo with its coppice woods. Murin-an had many deciduous trees, rather than the eternal pine trees, but also such novelties as fir (*Abies*) or *Torreya nucifera*. Lawns became *en vogue* for staging garden parties (Fig. 9).

Gardens in Japan,

Fig. 8 Visitors to a gardener's shop inspect the plants for sale (From *Ehon Edo Zakura* 1803 in. Kuitert (1999, p. 58)

The experience gained by gardener Ogawa at this job was put into wider practice in many other and larger gardens in the region around the temple Nanzen-ji in Kyoto. These gardens quickly became famous; most are still extant (Amasaki, 1990, 1992, 2007; Ono, 1987, 2000; Shirahata, 2008). The garden he designed at the Heian Shrine is typical of his work and shows us how he interpreted tradition in a contemporary way. The abundant use of flowers, notably iris, is remarkable, and – as in all gardens by Ogawa – water features are designed with much attention paid to details. Besides Ogawa, we find many other able landscape gardeners. Perhaps Jukki Iida (1890–1977) should be mentioned

here, as one of the men important in carrying the traditions over the Second World War. Iida invented a naturalistic style that could be produced cheaply and quickly, relying on a choice of plant material that would be called ecological today. Like Ogawa the feeling for the naturalistic landscape is central to his aesthetic of mixed deciduous trees (Ga-den raifu shuppanbu hen, 1977; Kuitert, forthcoming; Ogata, 1997). In the meantime landscape tradition had proved to be meaningful in developing urban parks (Maruyama, 1994). Tradition proved effective in large projects like the Meiji Shrine Park and the urban planning of Tokiwadaira (Kuitert, forthcoming).

Gardens in Japan,

Fig. 9 Murin-an shows naturalism achieved with artificial water and mostly deciduous planting (Photo by author 17 October 2013)

A garden artist negating this style was Mirei Shigemori (1898–1978). He was like a producer, working with gardeners rather than being a gardener himself. Therefore, as he was freer from tradition, he found a contemporary new definition of the dry landscape style, employing coarse white gravel and thick, dark green moss (*Polytrichum*). All over Japan he left us many of his at the time avant-garde gardens, some of them with strong lines and forms expressed in concrete (Tschumi, 2007). From an ecological point of view, his gardens are less successful.

The enormous economic expansion of the later decades of the twentieth century brought many commissions and big budgets. Landscaping became a large-scale operation of companies with nameless designers. Experiments with expensive materials such as worked natural stone, often set in concrete, mark this period. Although design was influenced by American

plaza design, the tradition remained meaningful. Ogawa's discovery of the deciduous tree and the coppice wood became common in parks, as well as in the private garden. Rock design remained strong, in some cases adding the strong line of the cutter, as can be seen in the Japanese Garden at the Expo site in Osaka.

The below list of sources gives references to this chapter and functions at the same time as a general bibliography that introduces additional sources for continued studies. Sources are in Japanese, and only in Western languages if they rely (more or less) on primary Japanese sources. Western sources on Japanese garden art have, throughout history, always showed interpretations that should be understood in view of the Western context. Some of these are included, as these are of historic interest, having in turn influenced views on Japan's garden art by the Japanese themselves. Some Western sources, as

Condor 1893–1912, contain interesting photos illustrating gardens and garden styles that have now disappeared.

Any serious researcher should refer to the volumes of *Zōen zasshi*, continued as *Randosuke-pu kenkyū*, and edited by the *Nihon Zōen Gakkai* (Tokyo) to find updated research results. *Nihon teien gakkaiishi*, edited by the *Nihon Teien Gakkai*, has often more detailed reports on individual gardens. One may also check my bibliography in *Themes in the History of Japanese Garden Art*, University of Hawai'i Press, 2002, or my *Gardens and Landscapes in Japan: 1650–1950* University of Pennsylvania Press (forthcoming).

Gardens of the Islamic World

Mohammad Gharipour¹ and
Anitha Deshamudre²

¹Morgan State University, Baltimore, MD, USA

²Syracuse, NY, USA

The study of landscape and garden design uncovers a deep understanding of natural order and the way it can impact human life. Through the various dynasties across the Middle East, North Africa, Spain, Turkey, India, and Southeast Asia, garden design was directly impacted by climatic responses, sociopolitical context, regional influences, existing topography and landscape, and functional adaptation. While there are numerous sources of poetry, art, and writings embedded in religious symbolism, the design of Islamic gardens and landscapes have served a wide variety of functional uses and also redefined the immediate built environment, surrounding landscape, and urban fabric.

The roots of religious symbolism of gardens traces far beyond Islam, from the Mesopotamians (4000 BCE), Babylonians (2400 BCE), and then to the contextual references of the Garden of Eden as a metaphor for Paradise in the New Testament within Judaism and Christianity. With the spread of Islam as a religion (seventh century CE), the Qurʾān also included metaphors of the Garden of Eden as eight levels of Paradise, filled with lush vegetation and the presence of

water. Although the symbolism of Paradise is rooted in religious aspirations toward the intersection between the metaphysical (represented in form by Nature) and the manmade, water and plant life are two central components that have both symbolic and utilitarian roles within garden design within this region. Although various studies have detailed the spatial configurations based on an inherent sense of geometric order and topography, an equal emphasis should be given to the study of the design of landscape, irrigation and infrastructure systems, and the socioeconomic progress from these agricultural practices.

Throughout the variations in form and function, the presence of water in gardens was a predominant symbol for purification, cleansing, and cooling, often depicted as the “rivers that flow beneath.” Although a vital source for plant life, the scarcity of water in the predominantly desert climates required innovative methods for extraction and distribution. Although influenced by earlier Roman aqueduct prototypes, *qanat* or underground systems of water wells and conduits strategically ducted flowing water from nearby rivers, streams, or groundwater to irrigate and sustain plant life. In addition, the inclusion of water channels and pools was a key climatic response as a passive cooling strategy especially in the tropical, arid desert climates of the Middle East and Southeast Asia.

Pasargadae, the royal hunting park complex of Cyrus the Great (559–530 BCE) from the Achaemenid era (550–330 BCE), was one of the initial traces of laying out landscape, and it set a precedent for garden design. Based on a composition of formal geometric order, this early work provided shade through vegetation and introduced early sophisticated methods of underground water conduits and irrigation infrastructure systems to provide for the diverse plant life. From ceremonial fountains and pools in the early courtyards of Umayyad Syrian royal complexes such as the Qasr al-Hayr (700–730) and Khirbat al-Mafjar (739–74), water continued to manifest through extensive systems of channels as a formal design element as well as the main source for the plant life to thrive. These private walled enclosures consisted of various functions

including a bathhouse, caravanserais, and a plot of land for agriculture (such as olives and other seasonal crops). The newfound capabilities of water access and infrastructure served as a catalyst in discoveries in agricultural and horticultural sciences as well as a supplemental economy and food source, even at a city scale such as under Abbasid rule of Baghdad (750 CE). This surge in agriculture through the advancement of irrigation technology and horticultural practices stimulated economic growth at an urban scale. However, gardens also served a wide range of other functions including pleasure, worship, hunting, leisure, as well as royal encampments, marketplaces, and urban redevelopment.

The relationship between garden and built pavilion elements was further developed in the Sassanid era in the palace of Samarra (849 CE). Other Sassanid palace pleasure gardens such as Firuzabad also further pursued water elements and pools. Palace gardens continued to develop extensively under Umayyad rule, such as the Madinat al-Zahra (936 CE) near Cordoba, Spain. Axial organization of gardens of various scales began to take form, where terraced views strategically placed on higher ground to create greater views of the exterior landscape. Divided by a series of interconnecting pools, colonnades, and pavilions, this complex set a new example for demonstrating the monumentality of palatial architecture and responding to the greater context of the surrounding landscape. These components that emphasized the grandeur and pleasures of royalty continued through Umayyad palace garden complex of Alhambra (twelfth century) in Granada, Spain, with its cross-axial water channels intersecting at a central rectilinear fountain aligned with lush shade trees and diverse plant life, surrounded by a marble colonnade of pavilions (Fig. 1).

In North Africa, gardens continued to vary as a prototype as open meadows within high walls under the Almohad rule (1121–1269) in Morocco. Located in a valley amid the Atlas mountain range, the Agdal Gardens (1157) combined private pleasure gardens with an open rectilinear plan of orange, lemon, fig, pomegranate, and other fruit orchards. Divided by interconnecting networks of tree-lined paths,

Gardens of the Islamic World, Fig. 1 Alhambra (twelfth century) – central rectilinear fountain surrounded by lush plant life and colonnade of pavilion structures

G

this vast garden complex depended on two major reservoirs for irrigation supply. Following the addition of the Dar El Beida palace in the early 1800s, the gardens served as places for royal enjoyment and restricted public access.

In Central Asia, following the successor Timur's (1370–1405) shift of the capital to Samarqand during the Timurid era (1370–1507), there was a surge in public projects and garden complexes. Stemming from Timur's nomadic lifestyle, some gardens outside the city boundaries were sites of royal encampment, as well court events and celebrations. In addition to permanent built structures, these gardens included tents, in the form of lightweight tensile structures. These sites of encampments, which were often laid outside the city walls, were also places of shelter and retreat during defeats in battle. However, the more permanent gardens within the main city were utilized for agriculture and economic benefits. These collections of temporary and permanent structures were yet another physical display of the growth of imperial power. While the city of Samarqand already had irrigation access from the Zarafshan River, Timurid gardens integrated waterways to organize geometrically a series of garden spaces with a central pavilion as in the cases of Bagh-i Bishisht (1378) and Bagh-i Shimal (1397). Later Timurid garden examples such as Bagh-i Dilgusha (1396) and Bagh-i Naw (1404) enhanced the geometric order through the use of planting beds ranging in species of fruit trees and plant life bordering the axial walkways.

Babur (1483–1530), Timur's grandson who later became the founder of the Mughal Empire, regarded garden design as a metaphor for the power of the imperial seat and constructed his first garden at Bagh-i Vafa (1508) in Kabul. The strong axial order and quadripartite geometry was an early prototype of the infamous chaharbagh (fourfold) typology. Overlooking the River Kabul, channels of running water divided four quadrants of diverse vegetation, including oranges, fruits, sugarcane, and other fruits. The chaharbagh, translated from Persian as "four gardens," flourished as a typology under Mughal rule, marked by the signature axial symmetry dividing the four distinct quarters by prominent waterways, representing the belief that there were four rivers that created the Garden of Paradise. While these gardens were used for religious rituals, camps, and royal events, the interpretation of chaharbagh began to represent the distinct Mughal funerary tradition, in which the garden that housed the tomb structure personified the resting place of the powerful imperial rulers. Such was the case of the tomb garden complex of Babur. Bagh-i Babur (1528) was located on the northern end of a complex consisting of a series of terraces aligned through an overarching longitudinal axis. Paved walkways known as *khiyabans* symmetrically divided the gardens into four parts, and water channels formed axial paths of the garden.

The chaharbagh typology continued to flourish at a monumental scale, through later Mughal

Gardens of the Islamic World, Fig. 2 Humayun's Tomb (1570) – chaharbagh plan flourished at a monumental scale during the height of the Mughal Empire

imperial funerary complexes such as Humayun's Tomb (1570) and the Taj Mahal (1631). In addition to refining the Persian prototype, Humayun's Tomb displayed the height of the Mughals' introduction of the mausoleum garden, as a key component of the funerary architecture tradition. In the elaborate development of chaharbagh, the core of the geometric order and symmetry of the 30-acre square site are marked by a system of cross-axial channels of running water and intersecting paved walkways, dividing the complex into 36 equal sections, converging at the central tomb structure. While the combination of cypress trees (representing death) and fruit trees (representing life) marked the main axial pathways of the complex, a greater amount of land was left open to create visual intensity and importance to the main tomb structure. This Mughal work also played a pivotal role in redefining the relationship between building and landscape, where the vast gardens and waterways radiated outward from the central monumental tomb structure, highlighting the power and prestige of imperial rulers over the people (Fig. 2).

The later Mughal emperor Jahangir (1569–1627) adapted from the earlier Mughal precedents and further developed the system of waterways, pools, fountains, and pavilion elements, through the royal gardens in Srinagar, Kashmir, at Shalimar Bagh (1641). Diverting

the water of the nearby canal from Lake Dal as the source for running water, the rectilinear plan is divided into four quadrants through its hierarchical water channels. Located on a sloped site, three main tiers (the lowest was a Public Garden, the middle was the Emperor's Garden, and the highest was the Zenana Garden), this terraced garden differed from earlier forms and prototypes, in that it adopted the surrounding mountainous topography. Each tier was unified by a central cascading water channel that dictated the main longitudinal axis and a set of water fountains at each level. Lined with sycamore trees, the central canal also houses arched pavilions (*baradaris*) and niches (*chini khanas*) behind the waterfalls at each terrace level.

Stemming from Babur's interest in plant life, garden complexes had a regionally adaptable species of fruit and flower species, such as citrus fruits, almonds, mangoes, and other Persian crops. Fatehpur Sikri (1569) and the Bagh-i Nur Afza (1620) are two examples of palatial garden complexes serving a variety of functions. The ruler and his establishment benefited from these horticultural experiments. These private royal gardens did have commercial potential, in that people renting garden areas could sell the fruit and flowers to common people. These funds in turn went to support the massive expenditure of the imperial tomb gardens, which was solely

intended for imperial symbolism and monumentality. On the other hand, private pleasure gardens owned by rulers or the nobility contained a wide diversity of flower and tree species and often followed the formal components of the garden plan, as in the case of the Bakhtawar Khan's garden (1667). Some Mughal gardens also served a fourth function in that they were open to the public, such as the Jahanara Garden in Surat (1648), which also included a caravanserai and was open to the public and visitors.

The use of elaborate small-scale pavilion structures and fountains continued to evolve in the Turkish gardens of the Ottoman Empire (1301–1922). While symbolic metaphors were shared with earlier Persian garden traditions, Ottoman sultans differed in that they created many private gardens for enjoyment and pleasure based on existing topographic conditions and irrigation sources, rather than relying on rigid geometric form and typologies. As in the case of Istanbul's royal Topkapi Palace Garden (1453), geometric fountains and pools were centrally placed, surrounded by a series of arched pavilions and a wide diversity of plant life (flowerbeds, herbs, fruits, and vegetables).

The Timurid influences of incorporating gardens on a city scale played a dynamic role in the urban reconstruction of Isfahan during the Safavid era (1502–1736). When Shah Abbas moved the capital from Qazvin to Isfahan, the design of the center city's streetscapes, city centers, and squares played a significant role in the shaping of the urban framework. In a city whose landscape was already fertile and well irrigated, the longitudinal axis of the main city center, the Naghsh-i Jahan Square (1598), was formed by the royal Chaharbagh Street laid along perpendicular to the Zayandeh River and subdivided by palaces, mosques, caravanserais, and arcaded bazaars. Becoming a thriving center for city activities, this prototype at Isfahan set a precedent through the adaption onto a grand urban scale and opened up the garden spaces for a multitude of public civic uses.

Gardens continued to develop and play a vital role in palatial gardens during the Qajar rule (1781–1925), such as the Eram Garden in Shiraz, Iran, which was restored under Qajar rule. While

ideas of formal geometric order, water elements, and pavilion structures continued to be embedded into the plan, an interest for diversifying vegetation surged including orange, pine, persimmon, and cypress trees. The desire for cooling was also addressed by creating channels of flowing water as well as pools of still water that served as a reservoir. However, in contrast to earlier works mostly marked by walled compounds, gardens of eighteenth-century Iran such as the Golestan Palace garden also gave priority to views to surrounding landscape and context. On a residential scale, the aristocratic house had garden complexes in the form of extensive courtyards outside city boundaries such as the Farmaniyeh House, Ghavam al-Saltaneh House, and Massoudieh House. These examples included ideas of pools, plant life, and hierarchical concepts of enclosed spaces and porches.

Between the thirteenth and eighteenth centuries, Arab traders migrated to various regions to the east, and this resulted in new empires and rulers in Southeast Asia, such as the reign of Sultan Hamengkubuwono I (1755–792). The Tamansari Water Castle complex (1758) in Indonesia consisted of a vast complex of gardens for private pleasure, royal defense encampments, hiding grounds, as well as several other smaller plots of landscape. With water as a central element, each of the spaces was linked through a series of geometrically shaped courtyards, drawing toward a central bathing complex.

Gardens have also played a dynamic role in the surge for urban regeneration and renewal of the late twentieth and early twenty-first centuries, in the form of open green spaces and public parks. As a part of the vast urban growth of Tehran in the mid-1900s, public city parks for recreation were created such as Niavaran Park, Laleh Park, and the largest Park-e Shahr. Containing some elements of traditional gardens of water, vegetation, and treatment of landscape, all of these parks were built for recreation and promoting civic life. Another such example is the Al-Azhar Park (1997–2004) in Cairo, which has open green space to rejuvenate the central core of the city while still paying homage to historic monuments, housing districts, and functioning as a part of the

modern infrastructure. Transformed from a central plateau of debris amid a dense historic city, this park reinterprets early Persian garden masterpieces through formal geometrical orchards, pavilions, lush vegetation, and open green spaces tied together by a continuous circulation path and several water pools and fountains. Contemporary gardens and landscape design for political projects such as the Dewan Negeri Johor (2003) and the Sultan Ismail State Parliament Building (2006) in Malaysia pull from early Umayyad design principles of formal geometric order and layers of spatial experiences to convey the changing role of government buildings.

From private enclosures for aristocracy to nodes of various public functions impacting urban growth, gardens emerged as a key facet of the built environment in the Middle East and Asia. Gardens of these regions have shown that they can become powerful illustrations of discovering nature's power and human purpose as they function through the design and adaptation of the landscape.

Gas: Exploitation and Use of Natural Gas in Premodern China

Hans Ulrich Vogel

Ancient Chinese sources give many references to strange fiery phenomena burning on water or

rising out of the earth. For instance, the *Hanshu* says that in 61 BCE the emperor sacrificed at the “fire well” (*huojing*) of Hongmen (Shaanxi). We do not know the cause of this fiery discharge, but it is clear that this fire well was an object of religious worship, because a fire well temple had been erected there. No mention was made of any use for industrial purposes (Fig. 1).

The first reports on the industrial use of a fire well come from the middle and late third century AD. One of these reports state that there is a fire well in Linqiong, Sichuan province. Once Zhuge Liang (181–234), counselor-in-chief of Liu Bei (162–223), came to see it, whereafter the fire turned stronger. People put pans on the well to boil salt. When brands of common hearths were entered into the well, it at once extinguished and did not burn again. Thus, it is clear that the prosperity and decline of the well was seen as corresponding to political developments. Another source, for instance, interpreted the extinction of the well as an omen for the annexation of Shu by Wei.

We cannot ascertain whether the Linqiong fire well was really a natural gas well, because later texts appear to suggest that petroleum was involved. Whatever the case, there is no doubt that it was productive for only a short period. That later authors referred to this well time and again is because it constituted a strange and interesting historical phenomenon. It is therefore hardly justified to speak of the “systematic use” of natural gas for evaporating brine “on an industrial scale” starting in the second or even fourth century BCE, as Joseph Needham claimed. Moreover, Needham also assumed that deep drilling, which was one of the preconditions for a systematic exploitation and use of natural gas, had already been invented during the first century BCE or AD. Recent research showed, however, that deep drilling originated in the middle of the eleventh century.

After the Linqiong fire well had become extinguished, probably in the late third century, Chinese sources do not mention the use of fire wells for industrial purposes until the sixteenth century. Although they still report on the outflow

Gas: Exploitation and Use of Natural Gas in Premodern China, Fig. 1 Fire wells of different quality, as shown on a mid-eighteenth century scroll. The scroll was photographed by Rewy Alley in Beijing in

1954. The location of the original is unknown (Photograph used with the permission of the Needham Research Institute, University of Cambridge)

of mist (*yanqi*) and hidden vapors (*yingqi*) from wells, it is clear that these discharges were conceived as threats to well salt production. For instance, in the tenth century explosive “hidden gas” was reported from the Ling well, a shaft well in the Lingjing industrial prefecture. Moreover, it is said that in the eleventh century, when workers had been let down into the well for repair work, they were killed. Only by the installation of a so-called “rain basin” (*yupan*) over the top of the well could these difficulties be overcome. From the rain basin water sprinkled down like rain, which carried the gas down into the well. This device was derived from the observation that gas discharge was restrained during rainy days.

Systematic use of natural gas began in the sixteenth century. In the beginning, the number and output of industrially used fire wells appear to have been still limited. Until the end of the eighteenth century a fire well usually could supply

fuel for only one to four pans, though exceptionally productive wells like the Yongtong well existed, which is said to have fed 16 pans. A scroll of the mid-eighteenth century shows interesting details of fire wells of differing productivity probably in northern Sichuan.

The standard situation appears to have been that one well was feeding one pan which was placed directly over the well. A ► bamboo tube inserted into the well served as burner. It was covered by a stone, in case the fire was to be extinguished. The scroll also shows a very productive fire well supplying two pans. The gas distribution device consisted of a large bamboo tube on which a porcelain vessel filled with water was put. The gas was distributed to the pans by two small pipes connecting the burners with the large bamboo tube. Finally, less productive fire wells not only could not feed more than one pan, but had also to be supported with firewood.

The situation changed dramatically with the development of deep drilling techniques in the nineteenth century, when the high pressure gas deposits in the deeper strata of the Ziliujing gas field were tapped. For instance, the French missionary Imbert reported in September of 1827 that a single fire well of Ziliujing could feed more than 300 pans and that the wells were so productive that a part of the gas could not be used and thus had to be burnt off. A new generation of productive fire wells supplying 400–700 pans is mentioned by Li Rong in his famous account of Ziliujing from the end of the nineteenth century. The use of the resources of such highly productive wells necessitated the invention of a number of devices for the control and distribution of the gas flow and for coping with variations in the well's pressure. The utilization of gas was a highly dangerous undertaking which could lead to explosions. That was also the reason why at least in Ziliujing gas was only rarely used for household purposes.

Natural gas was an amazing phenomenon which required explanation. Song Yingxing, in 1637, said that the fire wells contained simply cold water, but not the slightest evidence of the *qi* of fire. One can only see the notion (*yi*) of fire which is bursting forth from the burner's pipe, so that the brine will boil violently. Yet if the bamboo pipelines for conducting the gas are opened and examined, no sign of charring or burning can be seen. "To use the spirit (*shen*) of fire without seeing the solid form (*xing*) of fire – this is indeed one of the strangest things in the world" (Sun & Sun, 1966). Later Chinese authors had less strange ideas of the phenomenon of fire wells. For instance, in 1791, Xu Deqing came to the conclusion that the existence of fire and wind in the earth of high-lying terrains should be regarded as something quite normal, similar to the existence of fresh water sources in marshy and low-lying regions.

Ge Hong

Ho Peng Yoke

Ge Hong (ca. 283–ca. 343), alchemist, physician, astronomer, and government officer, was the greatest alchemist and physician in fourth-century China. We also know him under several other names, such as Ge Zhiquan, Zhiquan Zhenren, Baopuzi, and Xiao Ge Xianweng. His exact dates are not known with certainty. Some say that he was born between 280 and 286. Other dates given for his birth are ca. 253, 280, 281, 283, and 284. The year of his death has

been variously given as ca. 333, 340, 343, 361, and 364. Chen Guofu's elaborate study suggests the period 283–343 for him. Ge Hong's autobiography is contained in his *Baopuzi waipian* (Exoteric Chapters of the Preservation-of-Solidarity Master), but it says precious little about the author's scientific achievements. His biography is given in the *Jinshu* (Official History of the Jin Dynasty). Since he is regarded by the Daoists as having attained physical immortality, his hagiography is found in abundance in Daoist literature.

When he was young Ge Hong studied alchemy under Zheng Yin and Bao Jing, whose daughter he later married. He also learned much about medicine. He joined the government as an army officer in a military campaign to suppress an uprising in the year 303. After peace was restored he left without seeking reward and traveled widely in search of books. In the year 306 he accepted an invitation from his friend Qi Han to become his military adviser when the latter was appointed Governor of Guangzhou. Qi Han, the author of the *Nanfang caomuzhuang* (Records of Plants and Trees in the Southern Region) was one of the greatest botanists in traditional China, but unfortunately he was soon assassinated. Ge Hong remained for some time in the South and then returned to his place of birth, Nanyang, in Jiangsu province. A belated award came for his past service in the army. He was given the title Marquis of Guannei, and was recommended to the emperor for appointment as a member of the bureau of historiography. He declined the offer, but requested that the emperor make him magistrate of Goulou in South China, which was a rich source of cinnabar that he needed to prepare the elixir of life. Eventually the emperor granted him his wish. Ge Hong then went to live in the Luofoushan Mountain where he carried out his alchemical and protochemical experiments. It was probably there that he completed his famous alchemical work, the *Baopuzi*. Some say that the year was 317.

The *Baopuzi* consists of a *Neipian* (Esoteric Chapters) in 20 chapters and a *Waipian* (Exoteric Chapters) in 32 chapters. Among those in the *Neipian*, chapters 4, 11, and 16 are of special

interest to the alchemists, while the other chapters also contain bits of information on alchemy scattered here and there. Chapter 16 specifically describes the transmutation of base metal into gold or silver. Chapter 1 of the *Waipian* contains Ge Hong's autobiography. The rest of the *Waipian* says nothing about science or alchemy. The relevant sections in the *Neipian* contain names of more than 50 elixirs supposed to have various efficacies – some could only prolong the human lifespan, while others could transform the aspirant to a holy immortal varying from 3 days to 3 years depending on the elixir itself. Ge Hong seemed to be successful in aurification, the process of imparting an appearance of gold to base metals by artificial means. It is interesting that the attributes of the elixir of being a panacea, of being able to translate base metals into gold or silver by means of projection, and of being able to impart longevity and perpetual youth were already mentioned by Ge Hong in the case of some of the elixirs in his *Baopuzi*. Sulfur and mercury were used in many of his elixir recipes.

Ge Hong was an eminent physician in his own right. His *Baopuzi neipian* describes the medicinal values of many plants and minerals. During his stay at the Luofoushan Mountain he also wrote the *Jingui yaofang* (Prescriptions in the Treasury of Medicine), in 100 chapters. Later he added an abridged version, entitled *Zhouhou jiuuzufang* (Handbook of Medicine for Emergencies) in three chapters. Ge Hong's writings contain prescriptions for various types of diseases, including eye trouble, ailments of women and children, and infectious diseases such as smallpox and tuberculosis. They prescribed soya beans, cow's milk and goat's milk for the treatment of beriberi, and for treating bites from mad dogs the recommendation was to apply the brain of the culprit over the wound.

Ge Hong also showed considerable interest in astronomy. The *Jinshu* (Official History of the Jin Dynasty) quotes from a piece of his lost writings on the construction of astronomical instruments by ► [Zhang Heng](#) in the second century. It also narrates Ge Hong's participation in the great cosmological debate of his time. There were then two rival schools, the ► [Gaitian](#) (Canopy

Heaven) and the ► **Huntian** (Spherical Heaven). The former was more ancient and pictured a canopy heaven covering a square earth like a tilted umbrella. The latter visualized the earth as the yolk of an egg floating on water at the center of a spherical heaven that was itself supported by water. The argument used against it was that the sun rising from and setting into water would be quenched of its fire and heat. In supporting the *Huntian* theory, Ge Hong skillfully quoted the hexagrams and passages from the *Yijing* (I Ching, Book of Changes) to silence its critics. Ge Hong also observed the effect of the moon on the water in the sea and on the tides. In his *Baopuzi* he referred to the waves of the sea heaving up and down with the waxing and waning of the moon and the increase in magnitude of the tide when the moon was full.

Geodesy

Raymond Mercier

Geodesy, the measurement of the earth, is an essential component of both astronomy and geography. The spherical shape of the earth was a concept developed in the early stages of Greek

science, and one finds this concept wherever the legacy of Greek science was taken seriously. Figures for the radius of the earth were reported by Aristotle and a number of other Greek scientists, although a judgment of their accuracy is hindered by our ignorance of an exact measure in modern terms of the units in which the radius was expressed. The coordinates in Ptolemy's geography were fixed by him from various distances measured in terms of *stadia*, converted on the assumption that 1° equaled 500 *stadia*; for Eratosthenes, the degree equaled about 700 *stadia*. On the other hand sources in Latin and Syriac rather later than Ptolemy worked on the assumption that 1° equaled 75 Roman miles, which we can evaluate because the length of the Roman mile is well established, so we know that it is very precise. The radius and circumference of the earth follow immediately from the length of 1°.

In the early stages of Arabic science, especially the work heavily patronized in the early ninth century by the Caliph al-Ma'mūn, various Greek and Syriac sources were consulted with a view to fixing the earth's dimensions. Here the intention was to evaluate the degree in terms of the Arabic mile, which we know to be 4/3 Roman miles, 1,972 m. The Arab scientists of the time, however, were uncertain as to the interpretation of the various figures given in their sources, and they were certainly confused about the true length of the Roman mile. While they were aware that the Roman and Arabic miles were, respectively, 3,000 and 4,000 cubits, they were ready to assume that it was the cubits and not the miles which differed.

Against this background they set about to measure the length of the degree by direct observation of the latitude variations along a north-south traverse in the desert of Iraq. They chose a region south of Sinjār, which is about 100 km west of Mosul. According to extant reports two expeditions were made, one led by al-Marwarrūdhī, the other by 'Alī ibn 'Isā al-Aṣṭurlābī. In one account it is said that they agreed on the ratio 56 miles per degree, but other accounts of the expeditions report 56 2/3, or 56 1/4 miles. There is probably a blending here of observation together with a conversion of the

late Roman figure of 75, since $3/4 \times 75 = 56 \frac{1}{4}$. The accounts are somewhat lacking in circumstantial detail, and probably the methods employed, which must have involved a sufficiently portable quadrant for the measurements of latitude along the route, would not have sufficed to provide more than a rough verification of the received figures, sufficient at least to distinguish between the two different interpretations of the mile.

The great scientist ► [al-Bīrūnī](#) (fl. AD 1030) carried out some work of great value in his determination of a series of longitude differences for stages leading from Baghdad to Ghazna. These were reported in both his treatise on geodesy *Tahdīd nihāyāt al-amākan li-tashīḥ masāfāt al-masākin* (The Determination of the Coordinates of cities), and in his astronomical treatise the *Qānūn al-Masʿūdī*. He also reported his own attempt at a determination of the length of the degree. The latter took place in the Punjab, where the plain to the south may be seen from a peak (479 m) in the Salt Range, some 50 km South West of Jhelum. Al-Bīrūnī says that he measured the dip of the distant horizon as 34 min of arc, from which according to his calculation, he finds slightly more than 56 miles to the degree. He considers however that this should be regarded not as a new result but as a confirmation of the earlier result fixed at the time of al-Mamūn. In fact his procedure was flawed in various ways, for his measurement of the height of the mountain was considerably in error, and a correct interpretation would have required that refraction be taken into account. Moreover we may calculate, taking refraction into account, that he would have obtained a dip nearer to 29 min, so that his whole account is quite suspect. The method has been suggested independently by a number of scientists, but even when carried out with the greatest care, it is doomed to failure because the degree of refraction is unpredictable for a ray grazing the earth's surface.

Al-Bīrūnī's determination of the longitude differences was much more successful. The tables of mean motion in his astronomical treatise were referred to the meridian through Ghazna (near Kabul), and he was naturally obliged to determine

the time/longitude difference between that place and Baghdad. The primary information available to him, as to Ptolemy before him, was provided by travelers who would have converted a traveler's time to a distance. The region between Baghdad and Ghazna is divided up by al-Bīrūnī into shorter stages along two different routes, one passing North through Rayy and Jurjaniyya, and the other South through Shiraz. For each short stage, he calculated the difference of longitude, given the latitudes at each stage, and the distance from one stage to the next. In every case the travelers' distance is discounted to allow for the fact that the real path deviates from a perfect great circle. The problem of fixing the longitude difference is posed and solved correctly in terms of spherical trigonometry, and he gives all the numerical details, so that one can judge the accuracy of his work. In spite of occasional lapses in the calculation the results represent a very considerable improvement over that available in Ptolemy or ► [al-Khwārizmī](#); the final longitude difference between Baghdad and Ghazna is only some 15 min of arc short of the true value. People would not be able to improve on that until entirely new methods were discovered in the late seventeenth century, such as the use of Jupiter's satellites.

Geographical Knowledge in Ancient Sri Lanka

P. Wickramagama

Our knowledge about the early inhabitants who lived prior to the sixth century BCE in Sri Lanka is very limited, but more historical data is available for the period thereafter. Sri Lanka gained a place in the East-West trade and became an important centre in the sea route connecting the Far East and the West. It was known to people outside by several names (Lanka, Serendib, Sihladeepa, Taprobane, Seylon, Zeylon, Ceylon, etc.). Its proximity to the Indian subcontinent meant that people moved back and forth freely in ancient times. The Island has a long history of human habitation from about 130,000 years or more (Deraniyagala, 1998).

The island is divided into two major climatic zones, dry and wet, with a narrow belt in between with transitional characteristics. The Sinhalese civilization flourished in the Dry Zone, despite a severe water shortage during the long dry season. The highly seasonal rainfall meant rain-fed cultivation was possible only during the wet season. Despite this constraint, the main livelihood of the people was rice cultivation, which required considerably more water than any other crop. The need for artificial irrigation to overcome water deficit was understood from a very early stage, and the technology to develop a complex system of reservoirs and canals seems to have evolved out of this necessity. Development of irrigation demanded a high level of knowledge of the terrain as well as the principles of hydraulic engineering.

Sinhalese Cosmology

The ancient Sinhalese are thought to have known a great deal about the earth, its spherical nature, its position among other planets and the universe at large (Gunawardana, 1979). Sinhalese did have

close contacts with various parts of India and the Greco-Roman empire, particularly from the first century AD. Both ancient Hindus and Greeks had certain concepts of the earth, solar system, and the stellar constellations. Astrology played an important role in the ancient Sri Lankan and Indian cultures at a very practical level, and knowledge of astronomy was essential to make astrological calculations. It is possible that there was a considerable exchange of astronomical ideas between the east and the west. Verse 29 in *Sūryasiddhānta* says “This Brahma-egg is hollow; within it is the universe, consisting of earth, sky, etc.; it has the form of a sphere, like a receptacle made of a pair of cauldrons” (Burgess, 2000, p. 285).

Sūryasiddhānta also places the zero meridian (*madyama-rekha*) over Sri Lanka (Burgess, 2000, p. 362).

There is evidence that *Sūryasiddhānta* was one of the astronomical/astrological texts taught in the educational institutions of ancient Sri Lanka. *Girasandesaya*, a message poem, composed in the fifteenth century “describes how students at the Vijayaba Pirivena studied the *Sūryasiddhānta*, plotting the location of various planets by placing sea-shells as markers on a blue board and then moving them in accordance with their calculations” (Gunawardana, 1979). The *Vijayaba Pirivena* was one of the foremost educational institutions of Sri Lanka at that time. It is probable that the Indian astronomical texts were in use in Sri Lanka long before that. Further evidence of this can be found in *Sūryasiddhānta* itself, which speaks about exchange of ideas between students of astronomy in Sri Lanka and elsewhere in South Asia (Gunawardana). At the same time, their links with the Greco-Roman empire means they would have known the ideas of Greco-Roman philosophers. The Sri Lankan ambassadors who visited Rome during the reign of Emperor Claudius are known to have discussed the stellar constellations they observed in Rome and compared them with those observations back in Sri Lanka (Gunawardana).

Another piece of evidence of the Sinhalese cosmology and the shape of the earth is a carving in a cave in Anuradhapura (Fig. 1), which was

Geographical Knowledge in Ancient Sri Lanka, Fig. 1 *Sakwala* from a cave in Anuradhapura (After Bell, 1901)

discovered by archaeologists at the turn of the twentieth century (Bell, 1901), and was named *Sakwala* (earth or universe). It is a circular figure within which numerous symbols are carved and the outermost ring contains aquatic life forms. At the centre of the figure is a carving with seven concentric circles with a dot marking the centre. At this time, there was a belief that this was Mount Meru located at the centre of the world surrounded by seven oceans and four continents. It is possible that the figure with seven concentric circles represent the earth and seven oceans. The same concentric circles occur at the top of the figure as well. The other figures in the interior of the circle have not been identified. Wickramagamage (1995, p. 54) is of the view that this is a *yantra* which may have been used for meditation purposes. There is a seat made of stone right in front of this figure.

Ancient World Geography

The ancient Sinhalese maintained relations with countries in South Asia as well as the countries up to Rome in the west, and up to China and beyond in the east. This was facilitated by its strategic position in the east-west sea route. Seafarers from

the west and east came to Sri Lanka which acted as a trading post in the ancient world (Tampoe, 1995). Two other ports that participated in this trade are Gokannapatuna (Trincomalee) in the northeast and Magama in the south. Manthai (Near Mannar) functioned as the main harbour and as a great emporium in the ancient South Asia region. Sri Lanka sent its own ships to China (Tampoe).

Sri Lankan kings had established links with Greece and Rome as far back as the first century AD. The king of Sri Lanka (Bhatikabaya) explored the possibility of developing direct trade links with Rome. In the year 361 AD, an embassy from Serendivi was received by the Emperor Julian. Similarly, commerce between Sri Lanka and China goes very far back into history. Manthai was involved in transshipment of Chinese goods to the West. China-Sri Lanka trade relations were also reported by the Sinhalese ambassadors to the court of Claudius in the first century AD. Embassies carrying gifts from the Sinhalese king visited China in the first century AD. The relations with China were not confined to trade. There were cultural exchanges between the two countries. The countries with which Sri Lanka maintained relations include Greece, Rome, Egypt, Arabia, Afghanistan, and

Geographical Knowledge in Ancient Sri Lanka, Fig. 2 The world ancient Sri Lankan knew

Persia on the west and China, Korea, Japan, Malay-Indonesian Kingdom in the east (Bandaranayaka, 1998). At the same time relations with India remained at a high level. As Weerakkody (1997, p. 139) has pointed out Sri Lankans themselves had gone to foreign countries on business, and owned ships of considerable size. The Chinese writer, Kien Chang found people from Sri Lanka in Canton. Also a Javanese inscription belonging to the eleventh century mentions Sinhala merchants putting in at ports there (Weerakkody, p. 139). This evidence indicates that ancient Sinhalese knew a large part of the civilized world. The continents of Americas, Africa, and Australia were not known to them. The world they knew in ancient times is depicted in Fig. 2.

Knowledge of the Island

The dry lowlands of Sri Lanka received early waves of immigrants from India and continued to be the main areas of population concentration

up to about twelfth century. Although available evidence shows that the Wet Zone was inhabited since the Stone Age, evidence of major population centres is found only in the western lowlands, where the Kelani Kingdom existed. There are however some references to villages and places of religious importance in the Wet Zone. The Wet Zone highlands were a part of the *Tri Sinhale*, the three provinces the country was divided into. Distribution of stone inscriptions is often taken to indicate the distribution of the ancient settlements in Sri Lanka (Perera, 1978). The high concentration of inscriptions in the Dry Zone lowlands can be interpreted as evidence of ancient settlements in that area, and absence or low density of ancient inscriptions in the Wet Zone (both lowlands and highlands) may indicate that these areas were not densely populated at that time.

A number of villages were involved in various crafts and functions, such as industrial, agricultural, King's service, etc. According to Perera (1978) there were four types of settlements in ancient Sri Lanka:

1. *Gama*: Consisting of paddy fields, gardens, and chena. The people belonged to the same caste.
2. *Nigama*: Larger than *Gama* and a market town where traders met.
3. *Patun Gama*: More urbanized than *Nigama*. Both local and foreign merchants traded. These settlements were situated by the shore and usually had a harbour.
4. *Pura* or *Nagara*: Urban settlements, usually seats of government, with streets. Both local and foreign merchants met.

These villages were given names based on a salient characteristic of the village, and it is often its geographic character. There are many village names indicative of land forms, habitats, minerals, or man-made structures such as village tanks. The frequency of a certain name of a landform as a prefix or suffix to the village name indicates the dominance of that landform in the area. For example in the midcountry areas, there are many village names with ‘*deniya*’ which means a valley. This area is characterized by the presence of a ridge and valley topography, and the people have shown a preference to settle in such areas for the reason that they are suitable for paddy cultivation. Some villages are named after a dominant plant or animal species present in the area.

The island has been under one monarch from time to time or split into several kingdoms when there was no strong ruler to unify the country. Unification of the country led to wars which made it essential that the warring armies were acquainted with the terrain. From a very early stage, the different parts of the island were well interconnected by major routes. The chronicles and commentaries speak about five main highways. King Nissankamalla (1187–1196), according to an inscription, fixed *guavas* (2.25 English miles) on the main highways and laid inscribed stone pillars (Nicholas, 1959). Buddhist pilgrims from all parts of the island used to visit Adam’s Peak (*Sri Pada*) mountain on top of which the foot print of the Buddha is supposed to have been placed. Long distances were covered to reach the *Sri Pada*.

The *Sandesa Kavya* (Message Poems), composed in the Kotte period (fifteenth to sixteenth century), were written to dispatch a bird as a messenger with a message to kings and deities. The route to be taken by the messenger is described in detail in poetry, which contains a geographic description of the landmarks the messenger would encounter in its journey.

Cartography

The oldest known map that has survived goes back to the seventeenth century based on a claim by the person in whose custody it was kept (Fig. 3). This map shows “certain lands and the topography including the irrigation system in the valley of the Amban-Ganga, near Elehera, in the District of Matale” (Brohier, 1951, p. 192). It has been drawn on a closely woven fabric (40 × 80 in.). A reproduction of this map has been published by Brohier together with the corresponding portion of the 1-in. map of the area. The two maps show a remarkable resemblance. The scale of the map appears to be about 1 in. to a 1/4 mile, but this is not consistent throughout the map. The distances on the map are given in the Sinhala mile of *gauwa* which is about 4 English miles. The relative position of geographic features is accurate. There is no information about authorship of the map, or for what purpose it was produced. The directions are indicated in the map using the rising sun (east) and the waning moon (west). Brohier is of the opinion that the cartographer of this map was not familiar with the compass. If the author of this map learn the art of mapmaking from the Portuguese who were in the maritime provinces of Sri Lanka since 1505 and the Dutch later, he would have known to determine compass direction. Without more of such evidence, no firm conclusion can be drawn about the history of mapmaking in Sri Lanka. Given the need of such a practice in order to design irrigation canals, paddy lands, and reservoirs, it is conceivable that some form of mapmaking tradition existed in Sri Lanka. Maps may have been drawn on perishable material and therefore no evidence was left for the present generation.

Geographical Knowledge in Ancient Sri Lanka, Fig. 3 Sinhalese cartography (After Broheir, 1959, the English Text by the author)

Land Surveying and Design of Irrigation Systems

Without a clear understanding of the characteristics of the topography, construction of large reservoirs, tank cascades, and laying out of canals in an almost flat terrain would not have been possible. These irrigation works and their design can be used as indirect evidence of this knowledge. The early settlers of Sri Lanka chose the dry lowland plains for their settlements despite the severe water shortage during much of the year. This natural constraint was overcome by constructing first what is known as village tanks throughout the settled areas for irrigation as well as domestic use. Later, with an increasing population to be fed, it was discovered that these works were insufficient to last the dry season. This led to the development of large scale irrigation systems such as large reservoirs to store water by damming streams originating in the Wet Zone highlands. To convey water to paddy fields a system of main and distributary canals were constructed. They made decisions on the way canals are constructed, placing of sluices,

and constructing dams in an undulating plain taking advantage of the topography. This point can be illustrated using the example of the trans-basin canal, *Yoda Ela* (Giant's Canal), running from *Kala Wewa* reservoir in the *Kala Oya* river basin to the *Tissa Wewa* of *Anuradhapura* (the ancient capital of Sri Lanka) located in the *Malawathu Oya* basin. This canal has a gradient “for the first 17 miles (27 km) of 6 inches” (Brohier, 1979, p. 8). This shows the extent to which the ancient irrigation engineer understood the hydraulic principles and was able to convey water for long distances efficiently in a gently undulating terrain. Further evidence of the knowledge of the ancient Sinhalese engineer can be illustrated by a case where a branch canal from the *Yoda Ela* constructed by modern engineers some years back was later discovered to have run along the trace of an ancient canal which was used to irrigate the same lands using the water from *Yoda Ela*.

Another example for the extent to which the ancient Sinhalese understood the topography is the construction of village tank cascades in the Dry Zone of Sri Lanka (Fig. 4). “A cascade is a

Geographical Knowledge in Ancient Sri Lanka, Fig. 4 Ancient tank (reservoir) cascade systems near Anuradhapura

G

connected series of tanks organized within a micro-catchment of the Dry Zone landscape, storing, conveying and utilizing water from an ephemeral rivulet” (Madduma Bandara, 1985). They are constructed taking advantage of the topography along the tributaries of Dry Zone streams. There are 127 tank cascades in an area of 1,225 km² covered by the Anuradhapura and Medawachchiya 1 in. topographic maps alone. This amounts to one cascade per square km. Over 85 % of the operational tanks are located in cascades. The tank cascades allowed the optimal utilization of meagre water resources of an area. Each tank is associated with a paddy field, and the excess water from the paddy field returns to the tributary to be input to the tank downstream. The size of the tanks in a cascade tends to increase towards the lower end. The cascade system is reckoned to be one of the most efficient systems of water storage, conveyance and irrigation.

The ancient Sinhalese had a remarkable knowledge of the island as well as the South Asian region, and the countries in the west and the east. Their knowledge was not confined to the knowledge of places, but included such areas as the characteristics of the earth as a planet.

An area that should receive a great deal of attention and in-depth research is the knowledge the ancient Sinhalese had on harnessing water resources of the country. Construction of artificial irrigation systems of colossal magnitude and conveyance systems is a remarkable technological achievement. The most surprising of all is the ability to design these systems with such precision with minimal equipment. They seem to have had an intimate knowledge of the terrain which they utilized to the maximum extent in designing and constructing irrigation systems.

After abandoning these systems for largely unknown reasons, the population moved into the lower parts of the hill country and again used the topography of the terrain to their advantage to protect themselves from enemy attacks. The new settlements were established in the hill country which was completely protected by natural barriers, and entry was possible only through narrow mountain passes which were well guarded.

Although mapmaking would have been an immense help to the designers of irrigation system, no evidence is found on a cartographic tradition in Sri Lanka, except for a Sinhalese map attributed to the seventeenth century. This is

surprising given the fact that locating of reservoirs and construction of canals would have to be carefully designed and planned.

A substantial amount of original material is available for careful examination and study. It would be a rewarding exercise which could reveal depth of geographical knowledge of the people who lived in this island for over 3,000 years.

Geographical Knowledge in Non-western Cultures

Nancy Hudson-Rodd and Robin Rodd
James Cook University, Townsville, QLD,
Australia

Cultures differ in their assumptions about the nature of life, the place of their existence, and the place of humanity within their environment. Places, like space and time, are constructed socially and culturally and as such can provide ways to understand the literal and metaphorical geographies of humans. The specificity of place derives from the fact that each place is the focus of unique mixtures of wider and more local relations between social groups, and it is this mixture which accumulates continually to create the distinct place. While distinguishing labels, for people involved in these social relations, such as woman, Canadian, Maori, can be starting points, no one person or one group is exclusively one complete identity, Western, or non-Western, in the end of the twentieth century.

Human cultures are neither essentially coherent nor wholly homogeneous. The borders between nations, classes and cultures have become more fluid. The very notion that the majority of the world's population is defined by not being something (in this case non-Western) infers the continuing power of the past legacy of European and more recently American colonialism or imperialism. The majority of the world's population are non-Western. They did not

originate from Europe's colonial expansion into the Americas, Australia and New Zealand.

This geographical inquiry into the historical experience of non-Western cultures is made from the perspective of a Western woman, a cultural/historical geographer, born in Canada, now residing in Australia. A renewed concept of culture refers not to any unified entity. In a post-colonial world, the idea of an authentic culture as an internally coherent world is no longer tenable. Increasing global interdependence has made it clear that neither "we" nor "they", Western nor non-Western cultures, are neatly separated and mutually exclusive. All of us inhabit an interconnected, late twentieth century world, marked by porous national and cultural boundaries that are enmeshed with power, domination and inequality.

It is however, impossible to deny persisting continuities of long standing traditions, literate or oral, sustained habitation and cultural geographies of non-Western traditions. Human history is rooted in the earth. To understand this history, it is necessary to consider human dwelling and also to realize that European expansion meant the taking of land which was already owned by indigenous residents. With the beginning of European expansion in 1500, most indigenous peoples lived on their lands practicing agriculture, hunting and gathering. While all of these people have expanded geographically into adjacent territories, or into lands near where they once lived, there is no comparison with the great spread of people from European nations. It has been this modern colonialism which forced many indigenous peoples off their own land: Aborigines of Australia, Maoris of New Zealand, the indigenous peoples of North and South America. This compulsion of the Western world to explore, conquer, occupy and own other lands has involved such a long continuous process that it has been called the distinctive Western characteristic.

In contrast, a deep sense of belonging to the land, is central to the identity of indigenous peoples throughout the world, as exemplified by this Maori statement, that while "people disappear, land remains; land doesn't belong to the people,

people belong to the land" (Yoon, 1986). The names many of these First Peoples call themselves, such as Inuit, Maori, Saami, mean "people" and the names of their places mean "land". They literally know themselves as people of the land. "We have opted to become part of the environment", explains Burnum Burnum of Australia. Although differing widely in their customs, culture, economic status, physical surroundings, and impact on the land, many indigenous societies often share a set of values that are in marked contrast to Western priorities. The Cree of Quebec, San of Kalahari and Tukano of Brazil are all connected through a profound relationship and spiritual attachment with the land.

Human beings have created various cultural space and time systems in order to maintain their unique spiritual relationship with the universe. Before the dominance of Western ideas and colonial empires throughout the world, literate societies of Japan, China and India were eloquent in describing their human relationship with non-human species and their place within the greater environment. Oral traditional societies had highly developed constructions of their environments which were transmitted through stories, dance and by paintings to successive generations. For non-Western peoples, although widely different in customs, culture and impact on the land, there was a shared belief in a deep bond with nature, an awareness that all life, rivers, skies, people, ants and rocks were inseparably interconnected. Physical and spiritual worlds were woven together in one web. Humans were not separate from nature but were a part of the nature of the world. Geographical knowledge concerning human and environmental nature is always socially and culturally construed. Through specific examples from non-Western cultures of both literate and oral traditions, an understanding of the diversity of specific geographical knowledges can be explored.

The Mythic Creation of the World

Each culture possesses creation myths which speak of the creative beginnings, an energetic

phase prior to the appearance of physical matter and life. Marriage between the Ancestral couple is common to creation myths of India, Egypt, Mesopotamia, China, Central America and New Zealand. In all these myths, creation is sparked by a cosmic copulation. The intercourse of Geb and Nut in Egyptian mythology and that of Shiva and Paravati in the Indian myth, and Ranginui and Papatuanuku, the primeval pair in Maori myth, reflect creation themes. The vision of the sacred earth as a ledger of cosmology is unique to Australian Aborigines with their creation story written like a book in the earth's topography.

There is evidence of great length and complexity in Australian Aboriginal culture, the oldest continuing society in the world, reaching back to the Pleistocene Age which is based on the remembrance of the origin of life. Aborigines speak of the forces and powers which created their world as Creative Ancestors. During this epoch of world creation called the Dreaming, the Ancestors travelled across a barren flat terrain. Their hunting, loving and fighting shaped the land, deeply marking the surface of the earth and leaving their imprints forming the topographical landscape, making riverbeds and forming rocks and deserts. Before their travels, the Ancestors would sleep and dream the adventures of the following day. In this way, moving from dreaming to action, they had the ability to alternate between pure spiritual powers and an apparition of other forms. In Western scientific language, the earth evolved through a phase of powerful geological and climatic forces which shaped the earth's crust, creating mountains, oceans and rock formations. The main difference between these two myths is that Western scientific description acknowledges only physical forces, while Aboriginal explanation attributes consciousness to the creative forces and to everything created.

The Dreamtime epoch concluded with three fundamental conditions making possible the embodiment of conscious life: the earth's distinct topography, all variety of species of life, and patterns for social relationships. With the completion of this task, the Ancestors grew weary as the world was shaped and filled with species and

varieties of ancestral transformations and they retired into the earth, the sky, the clouds and the creatures to exist like a potency within all that they had created. Their journeys were preserved in stories, paintings, ceremonies and patterns of living and extended a universal psychic consciousness to every living being as well as to the earth and the primary forces and elements.

The Western tendency to view land as material object, existing separately from humanity, allowed for it to be bought, sold and exploited. In contrast, Aboriginal culture shared the identity of the forms, principles and activities by which the natural world was created and saw life and sustenance embedded in the landscape which must be cared for as a friend and provider in continuing reciprocity. "With the birds, the fish, the animals, the plants and all of nature we are still Yorro Yorro, standing up in accordance with the blueprint of Creation", explains Mowaljarlai, concerning the role of men in maintaining the connection between cosmic regions and earthly community life in the Kimberley, Western Australia.

Understanding Nature and Humanity

Generally, the Japanese philosophical and religious traditions represent a holistic ecocentric view characterized by an aesthetic and material oneness with all things. In pre-industrial Japan, the intimate relationship between people and their surroundings can be grasped by the Japanese word *fudo*, which translates into the natural environment. While nature and humanity have been viewed as separate but connected in Western thought, *fudo* refers to the idea that nature and society are inseparable. *Shi-zen* or *Ji-nen* is the Japanese word which most closely corresponds to the European term nature. The connotations of this term signify a concept of nature in which nature is not objectified. Rather, *Shi-zen/Ji-nen* represents the manner of being and becoming of nature, human and environment. *Shi-zen*, originally a Chinese word, was adopted by the Japanese about 1,500 years ago. In ancient Chinese culture, the term had fundamental significance. Lao-Ze wrote: man is based on earth, earth is

based on heaven, heaven is based on the Way (*Dao*) and the Way is based on nature (*Zu-ran*, or *Shi-zen* in Japanese).

The contrast between European and Japanese garden design illustrates the difference in perspectives of nature. In the English garden, a person seeks escape from humanity into a natural space free of artificiality. In the Japanese garden, one tries to express, within a defined space, the totality of mountains and rivers. This is an artistic, human act representing the highest meaning of *Shi-zen*. The English garden is a public place, open to all. The Japanese garden is of a private nature created solely for the few who are artistically gifted. Nature relates equally towards all in the English garden. The *Shi-zen* of the Japanese garden requires those who are able to experience *Shi-zen*. This implies that *Shi-zen* can never be separate, but within the person.

It is the same for Ikebana art and the *Shi-zen* of the tea-ceremony. In the Japanese tea-ceremony, the everyday routine becomes an art form. Sitting in a quiet, small room allows for the mind and body to become alert to the slightest sound, movement of the wind, perfume of flowers, changes in the intensity of light. This time passed within a small room heightens the sense of place by creating a moment of spiritual connection with the environment.

Sense of Place

The sense of place exists in the area where nature and humanity interact and shape each other. Within cultures, information concerning the geographical environment is expressed in certain ways, such as the making of maps, conceptualizing landscapes, and giving places names. In the Pintupi language of Central Australia, a place, or a country, or a camp is called *ngurra*. *Ngurra* signifies both the physical place where people share food, sleep, and dance, and also the metaphysical act of dreaming the country into existence. In this way, the question of Aboriginal identity is obtained by knowing the place. As Kuningga, the ancestral cat, travelled north he crossed plains, identified water sources and, after reaching a

ceremonial site, continued north through a gap in the range. Kuningga's dreaming track weaves north, describing the particular geography of the land and of the natural resources contained within through a song cycle. Thus Kuningga's song can be understood as an oral map of the country. Places where significant events happened, where power was stored, or where the Ancestors had retired into the ground and still remain today are known as *Yarta Yarta* or special sites because of their concentrated ancestral potency.

Certain landscapes create a sense of awe by their presence. In Japan, Mt. Fuji, rising 13,000 ft above sea level, has been depicted in poems, paintings and stories from ancient times. The sheer physical presence of mountains which appeared to connect the earth with the sky allowed for them to be considered Japanese shrines. The word *oyama* sometimes means shrine and is derived from *yama* (mountain). Tadahiko Higuchi in his book *The Visual and the Spatial Structure of Landscape*, described seven prototype shapes for shrine and temple complexes which were translated by Kazuo Matsubayashi. They are:

1. Water-distributing: where water flowed out of the mountain creating a perfect rice irrigation place
2. Bowl: a small, peaceful, plain surrounded on all sides by green mountains
3. Lotus Flower Calyx: the site of a mountain temple surrounded by eight other mountains, which resembled the calyx of a lotus
4. Wind and Water (*fusui*): usually having mountains to the north, hills to the ► east and west, and a sea or river to the south, which was the ideal place to build a city, house or tomb
5. Valley: enclosed by mountains on both sides, which was thought to be the home of the spirits of the dead
6. Thickly forested: a small mountain covered in thick foliage in sharp contrast to its situation near a flat plain, which was believed to be the sacred dwelling of a god
7. Country-viewing: a low hill or mountain standing in the middle of a plain, commanding a view of the surrounding land

The close relationship between the people and their mountainous environment, with each of the types serving a unique purpose, demonstrates the vital reciprocity between humanity and nature.

In Maori tradition, the special relationship between people and their land is revealed, first by the myths explaining the origin of the universe, in which the material world proceeds from the spiritual and the spiritual world interpenetrates the material, physical world of Te Ao Marama, and secondly by the use of dominant landmarks, mountains, or water sources, as symbols of tribal identity. While many indigenous peoples live intimately with nature, the Maori appear to be unique in their formulation of their *pepeha* or popular sayings of tribal identity. Every established Maori community may apply their standard *pepeha* or introduction by naming their mountains, river and tribe at intertribal meetings, now as in the past, actively maintaining the oral tradition and identity of place.

Makeo is the mountain – Ko Makeo te manunga
 Waiaua is the river – Ko Waiauna te awa
 Tutamure is the Ancestor – Ko Tutamure te tangata

Hong-Key Yoon has described the pattern of structure of these sayings which includes the first two phrases for natural identity in terms of landscape and the third for cultural identity in terms of people. The first phrase mentions the most significant landform, almost always a *Maunga* or mountain followed by the second phrase giving the name of a prominent body of water or *te wai*, *te awa* or river, *te awauni* or big river, and *te moana* or sea. The third phrase names the tribe, giving social and cultural identity. Maoris associated intense feelings with the mountains, considering them to be the place of buried ancestral bones, while the valleys and rivers, often serving as tribal boundaries, did not assume as intense a sanctity.

These *pepeha* revealed the symbolic relationship of the people within their place and were combined with the functional territorial boundary delineating home territory, while also perpetuating cultural heritage. Today, the Maori traditions

of respect for place are represented by the Maori Secretary in the Ministry of the Environment. The name of their movement, *Maruwhenua* comes from the understanding of the human responsibility for protecting the land. Mmaruwhenua reflects the saying, "People perish, but the land endures".

Sustaining Natural and Human Place

Indigenous knowledge of nature has ensured the survival of many peoples living in fragile habitats. For example, the Tuareg of West Africa practice nomadic pastoralism in a land so arid that it cannot sustain continual habitation, and the Inuit of the frigid Arctic regions have traditionally depended on hunting and fishing. Modern hunting and gathering depends on cooperation between group members and the formation and maintenance of economic relations with other groups. In Ituri, the tropical rainforest of northeastern Zaire, a mutually supportive, economic relationship has been created between the Efe, who practice a semi-nomadic lifestyle, and the Lese, who live as shifting cultivators. The Efe trade forest products, nuts, construction materials, meat and fish for produce grown by the Lese, and for their pottery, tools and arrows.

In many areas of the world, indigenous societies have classified soils, climate and animal species. Many of these words and descriptions for insects and plants are yet to be known by botanists or entomologists. The Hanunoo people of the Philippines distinguish 400 more plant species in their forests than the 1,200 ones identified by the scientists working in the same location. The Kayapo of Brazil gather about 250 types of wild fruit, hundreds of tubers, leaves, and nuts, and at least 650 plants which are used for medicinal purposes. This vast, complex, indigenous knowledge is now viewed as being important not only to the sustenance of the traditional owners, but to the very survival of the world.

The human relationship to the natural environment has been conceptualized differently over time and through space. At the end of the twentieth century, understanding of the human

experience of nature, from both a Western and non-Western cultural tradition, has become an urgent imperative. The challenge now is to regard humanity and earth in global terms while also seeking an understanding of the social and ecological implications of the whole of humanity planetized. There has been much discussion concerning the damaging perspectives of the Western, anthropocentric approach to nature which has led to actions based on a premise of the separation between mind/body, human/nature and individual/society. This view has been blamed for much of the environmental destruction and exploitation of the world's human and natural resources. At the same time, there have been appeals to consider alternative modes of conceptualizing humanity and nature, such as developing a reverential attitude towards nature and acting in a socially cooperative manner, based on a non-Western, ecocentric perspective.

Cultural expressions, Western or non-Western however, show a universality only at the broad structural level. To go beyond this, it is necessary to explore the specific historical contexts of human habitation in place and through time. Non-Western and Western cultures are historically dynamic. It is important therefore to emphasize the particular and convey the diversity of traditions within and between groups, in order to create mutual understanding.

Geography in China

Mei-Ling Hsu

The term geography (*di li*) which first appeared in Chinese documents during the Spring-Autumn period (770–476 BCE) literally meant the study of the order and morphology of the land. In the beginning the purpose of such a study was for survival; later it was used to facilitate the production of food and gathering materials for shelter. Agriculture was central to the economy, hence information was collected on climate, land, and water supply, and for crop cultivation and water control, e.g., to construct dikes. Because of these needs, studies in “geography of production” increased. Thus the Chinese have accumulated much geographic knowledge since ancient times.

The two frequently cited geographic classics are *Yu Gong* and *Di Li Zhi*. They demonstrate the importance of geography in delineating major regions in the country and in collecting locational information; these geographical applications facilitated the governing of the ancient Chinese empire. Mapping of large regions and local areas followed.

Yu Gong (The Tribute of Yu, who was a semi-legendary emperor) is a short but brilliant work, written in the Warring States period (475–221 BCE). It presents chapters on mountains and rivers, and on two methods of organizing geographical space: delineating nine physical regions, and allocating five political regions in China. Thus this work presents the earliest examples of regional and systematic geographies.

The term geography was first used as a title of a work in *Di Li Zhi* (Treatise of Geography), a chapter in the *Han Shu* (History of Han Dynasty), by Ban Gu (AD 32–92). It includes three sections, of which the first and third were reprints of earlier works, including *Yu Gong*.

The second section is devoted to the geography of 103 prefectures (*jun/guo*) and their sub-units, the 1,587 counties. Within each administrative unit, some physical, cultural, economic, and demographic features are described. Cities are mentioned. Interestingly, it also describes petroleum as some kind of liquid that can be burnt. However, the major focus of this work is on the history and changes of boundaries of administrative divisions and settlements; such information was important to the governing of a large empire. Unfortunately, too often this particular focus was emphasized at the expense of a more thorough treatment of the physical characteristics of an area, and their effects on the inhabitants and the economy.

The publication of *Di Li Zhi* marked the beginning of a chapter on geography to be included in a dynastic history; this chapter appeared in the second of the 24 such histories. Thus the content and the methodology presented therein became a model that was followed in the later dynastic histories.

Ban Gu's work also planted the seeds of a later development: the publication of local gazetteers (*di fang zhi*) with maps included in these volumes. Beginning in the fifth century, the production of these gazetteers increased in number and gradually became the most prevalent form of geographic writing and compilation in pre-modern China. During the Tang Dynasty (AD 618–907), the scope of some gazetteers began to expand to cover a province and even

the whole country; some of these compilations were multi-volume and were really geographical encyclopaedias. Today they constitute a voluminous geographical and historical literature.

Beginning in the Tang Dynasty, field studies became more important. Perhaps, by this time, long distance travel in China had become more manageable. Noted scholars spent many years away from home travelling and studying the country. They left with us their vivid descriptions and insightful interpretations of the geography of China. Among these books, the best known is the *Xu Xiage Yuji* (Dairy of The Travels of Hsu), written in the seventeenth century. Thanks to the efforts of these scholars, accurate geographical knowledge was accumulated, e.g. of the source of the Huang River, the process of erosion, and the retreat of the sea in the area of today's eastern lowlands. The last of these was studied by Shen Gua in the eleventh century; similar observations to that of Shen's were made in Europe by J. Hutton in the nineteenth century.

Despite the richness of the pre-modern literature, geography was not formally included in the civil examination in imperial China. Only during the late nineteenth century, as the modern school system was developed was geography incorporated as an instructional subject in schools. Today, in Taiwan and on the Chinese mainland, geography courses, which vary in area coverage and degree of difficulty, are taught in every grade in the secondary schools. The two major purposes of this instruction are to provide students with basic knowledge of China and of other countries in the world and to foster the spirit of patriotism.

In historical China, geography and cartography played important roles in scientific inquiry and applications. In this century, the subject geography is taught in schools and colleges, and mapping activities are routinely carried out by government agencies and educational institutions.

Geography in India

Ashok Dutt and Meera Chatterjee

The study of geography as a systematic science was a significant gap in Indian knowledge during ancient times. However, geographical facts were presented in a nonsystematic manner in the whole range of Sanskrit, Pali, and Prakrit literature. Compositions of a geographical character are often found embedded in the religious, legendary and astrological literature of ancient India. Both religious and secular literature contain numerous

isolated references to cities, mountains, rivers, regions, and society, which collectively amount to a considerable addition to geographical knowledge. India is the home of an ancient civilization that originated over 5,000 years ago and attracted many travelers, scholars, ambassadors, and missionaries. Many conveyed impressions back to their compatriots through lively tales, anecdotes, and travel journals. These writings also became important sources of geographical knowledge. The writings of the Chinese, Greek, and Arab geographers are rich sources of information relating to various aspects of geographical science. Various names such as *Bhuvankosa* (Terrestrial Treasure), *Trilokya Darpaṇa* (World's Mirror) and *Kṣetrasamāsa* (Combination of Countries) were used to denote geographic phenomena. Hence, the principal sources of information about the status of geography in ancient India are sketchy because they are obtained from references extracted from nongeographical works, foreign accounts, and inscriptions. The ancient literature developed over the centuries could easily be arranged in a chronological sequence. *Ṛg Veda* (about 1500 B.C.E.) was the first, which was followed by three other Vedas, *Sama*, *Yajur*, and *Atharva*. The *Upaniṣads*, *Purāṇas*, *Jātaka* tales and great epics – *Rāmāyana* and *Mahābhārata* were composed between 1000 and 500 B.C.E. Kautilya's *Arthasāstra* was composed around 300 B.C.E. Other than these, there are writings of different poets and foreign people that also help us to infer the geography of ancient India.

The *Ṛg Veda* is the earliest Indian literature that has been discovered. It mentions many geographical facts such as tribes, rivers, and mountains. According to ► Al-Bīrūnī (Alberuni), an Arab traveler in India, “Veda is knowledge of that which was unknown” (Kazmi, 1995, p. 41). These and associated books contain knowledge about philosophy, mathematics, medicines, navigation, music, and dance. The *Upaniṣads* are works on religious meditation (Tamaskar, 1985). It is difficult to find any direct description of the earth or the world, but, as in the *Ṛg Veda*, geographical phenomena or features are embodied in them. Like the *Vedas*, the *Purāṇas* also did

not deal with geography in a systematic manner; however, they have a lot of geographical facts in them. The scientific material covers a wide range of topics from astronomy, cosmography, and cosmogony to the classical concept of region and regional classification. As defined by Alberuni, *Purāṇa* means “first eternal” and the *Purāṇas* are associated with the names of animal, human or angelic beings. *Purāṇas* not only contain mythical and legendary materials, but also contain scientific information, which is sometimes accurate. Information about astronomical geography can be easily extracted out of the *Purāṇas*. *Jātaka tales* are a huge source of unsystematic geographical information. The legendary stories contained in the *Jātakas* relate the previous lives of Gautama Buddha, the founder of Buddhism. He lived and preached in northeast India between 563 and 483 B.C.E. As there was no written common language, the stories were memorized and handed down from generation to generation by word of mouth. Several hundred years later they were written down in the Pali language; in the process many facts were exaggerated or lost. The *Jātaka* tales were set in some contemporary kingdoms. Kautilaya’s *Arthaśāstra* mentions the names of a few mountains, regions, and tribes. It also provides us with a lot of information about territorial sovereignty and geopolitical principles. The great epics *Rāmāyana* and *Mahābhārata* contain extensive geographical descriptions of north and south India, military geography, family structure and the presence of non-Aryan tribes. (*Mahābhārata* depicts the war that occurred about 900 B.C.E.).

The Aryans, who brought the *Ṛg Veda* from outside the borders of India (possibly from Persia), first settled in northwestern India (Punjab and the Indus plain). They mentioned regional rivers and their branches, such as the Saraswati (extinct), Sutudri (Sutlej), and Sindhu (Indus) (Fig. 1). The rivers, seas and regions had different names in ancient India. A few of them are mentioned in Fig. 1. According to *Ṛg Veda*, Saraswati was the greatest and most powerful river that flowed from the mountains to the sea. The greatest and the holiest river mentioned was not the Ganges, but the dry Saraswati. The latest

studies have shown that the *Ṛg Vedic* Saraswati was a perennial river. The confluence of the Ganges (Gaṅgā) and its tributary Yamuna are mentioned as the eastern boundary of the Aryan settlement. However the Ganges was mentioned only once, whereas the Saraswati was mentioned many times.

By the beginning of the Christian era, three other Vedas, epics and *Purāṇas* were written, and a more extensive description of Indian geography evolved. The Aryan settlements advanced eastward all the way to Bengal and toward southern India. The latter, though Dravidian in terms of linguistic and physiognomic characteristics, became Hinduized.

Ṛg Veda set the layout of an important aspect of social geography by stratifying Indian society into four different castes. (1) *Brahmins*, who were the interpreters of religious texts and handled all the scholarly literature, (2) *Khasatriyas*, the warriors and the rulers, (3) *Vaiśyas*, the merchants and farmers and (4) *Śūdras*, slaves who did all the hard work including cutting jungles to make land arable. Some of them were designated as untouchables. The following extract is based on *Ṛg Veda* explains the function-based, social hierarchy (four castes).

The *brahmins* form the highest social order, the literate intelligentsia which gave India its priests, thinkers, law-givers, judges, and ministers of state. The *rajanyas*, later called *khsatriyas* or rulers, were the second social order. The Indian counterpart of feudal nobility: from this class was recruited kings, vassals and warriors. The *vaishyas* formed the class of landowners, merchants, moneylenders, while the *śūdras* originally those people conquered by Aryans, were workers, artisans, or serfs. (*Ṛg Veda*, 10.90, as cited in De Bary, 1967, pp. 13–14.)

The caste system still persists among the Hindus. As most of the Muslims and Christians in India are converted from Hinduism, many of them have retained their caste distinction.

Ancient Indians also knew about the land and water ratio on the earth’s surface. Though they did not have accurate knowledge of the ratio, they believed that oceans occupied twice as much area as the land surface on the Earth. In the second

Geography in India, Fig. 1 Rivers, regions, and maritime features of South Asia (Base map from Dutt & Geib, 1998. Permission obtained from the copyright holders.

Anuwaka of third *Brāhmaṇa* of III *Adhyaya* of the *Bṛihadāranyaka-Upaniṣad* it is said, “The oceans surround this earth on every side twice as large” (Tamaskar, 1985, p. 7).

The authors gathered the information on the names of the ancient rivers from various sources)

The Himalayas were mentioned in *Upaniṣads* as the “White Mountains” because their upper reaches are snow clad year-round. The rivers flow out of this mountain chain in an

► east and west direction. They have also been referred to as a powerful barrier for invaders, thus acting as natural borders.

The river Ganges is mentioned in the *Vayu-Purāṇa* as a purifier of sinners, passing through thousands of mountains and irrigating hundreds of valleys thus establishing the importance of rivers in the environment. *Matsya-Purāṇa* also mentions the rivers of Jambū-dvīpa (consisting of most of Asia) and Bharatvarsha or India (the southernmost country of Jambū-dvīpa) rising in the ranges of Himavanta (Himalayas). It was in *Kausītaki* that the southern mountain – Vindhya – was first mentioned, while both *Vasishṭa Dharmasūtra* and the *Code of Manu* referred to the Vindhya by name. *Rāmāyana* and *Mahābhārata* give extensive descriptions of geographic features of both north and south India. When King Dasaratha (in *Rāmāyana*), father of Rama, performed an *Aśvamedhayajña* (Horse Sacrifice) to establish his supremacy over the world, both north and south Indian kings were referred to. In the *Bhīṣmaparva* section of the *Mahābhārata*, Sañjaya, the chariot driver of the blind king Dhṛitarāstra, identified the nations, mountains, and rivers of India. Epics also describe Hastināpur (situated by the side of Ganges), capital of the Kauravas, Indraprastha (situated by the side of Yamuna), capital of Pāṇḍavas, Ayodhyā (in Uttar Pradesh), capital of Rāmā and the city of Mithilā (in Nepal terai). In the *Rāmāyana*, the city of Mithilā, possibly Janakpura in Nepal terai, is referred to as a “city of color and pleasure with people enjoying the business of living.” It had “golden turrets and domes, and lofty towers.” The book also says that, on the eve of Sītā’s *Swayambara* (a ceremony in which the princess selects her groom from among the invited guests), there was a “moat” surrounding (King) Janaka’s palace (Narayan, 1972).

The *Jātaka* tales were set in some contemporaneous kingdoms. The topographic features are embedded in the tales. The Himalayas were mentioned many times. References to small water bodies (ponds) can also be found. Mostly the stories were woven around animals; this referred to the conservation of wildlife. The tales

mentioned the coexistence of carnivores and herbivores, a condition required in nature for a balanced ecology. They frequently refer to thick forests which indicates that the Himalayan and sub-Himalayan zones and parts of the Deccan plateaus were once covered by dense and luxuriant forests. Numerous species of plants and trees were also mentioned. Cultivation and rearing of animals were the principal occupations of the population, although there is a mention of nonprimary activities, such as mining, textiles and trading. The *Rg Vedic* literature talks about the abundance of water in North India brought about by melting of ice caps. Present arid regions like Thar and Rajasthan deserts and the deserts of Sind were once fertile and supported agriculture.

Permanent settlements and agriculture led to trade and other occupational differentiation. Aryans after settling in Pañchāla (Punjab and Haryana) started colonizing the central and eastern Ganges plains and advanced to the Ganges delta in Bengal. From east to west there is a progressive diminution of Aryan traits among the population. As the Aryans advanced eastward, more slaves and śūdras (tribals, vanquished people and Dravidians) were used to clear forests in order to make the Ganges and other plains cultivable. The eastward terrain was inhospitable, wet and disease laden and had limited attraction to the Aryans. They employed slaves and śūdras in vast numbers, who performed the most difficult task of land reclamation. As lands along the Ganga (or Ganges) were cleared, the river became a trade route; the numerous settlements on its banks became markets and trading centers. The cities of Varanasi and Pāṭaliputra (Patna) are two important examples. As the majority of the settlements grew up along the river the probability of their being linear was very high. Trade was restricted initially to local areas, and barter was an essential component of trade, cattle being the unit of value in large-scale transactions, which further limited the geographical reach of the trader. Consequently, markets and the trading process were concentrated in some regions. Custom was law, and kings and chief priests were the arbiters, perhaps advised by certain elders of the community. An Aryan *rājā*, (king) was primarily

a military leader, who took a share from the booty after successful cattle raids or battles. Although the *rājās* had managed to assert their authority, they scrupulously avoided conflicts with *Brahmin* priests as a group, whose knowledge and austere religious life surpassed others in the community. The priests were the educated group of the society and considered superior to other castes, and they also interpreted religious books.

Kautilya's *Arthaśāstra* prescribed a state planned colonization policy for undeveloped (primarily natural vegetation covered) areas with people from foreign lands and kingdoms' surplus labor. Each village was to have 500 families, mostly śūdra cultivators or laborers; villages were to be grouped in a hierarchy of settlements of 800, 400, 200, and 10 units with a large town (*sthaniya*), small town (*dronamukha*) smaller town (*karvatika*), and large village (*samgrahara*) to serve each group, respectively.

Beginning with the *Ṛg Veda* through the *Purāṇas*, cosmological and cosmogonic interpretations of the causes of wind, precipitation, day and night, seasons, and the planetary movements were made. A four-way explanation of the origin of the universe was also given: artistic, mechanical, instrumental, and philosophical. First, the artistic origin refers to god as an artist who skillfully constructed the universe. Second, the mechanical origin is conceived as a sacrifice of the *Ādipuruṣa* (primeval body) who not only had the soul and the nucleus of the universe, but also embodied the Supreme spirit, resulting in the formation of the earth, sky, wind, moon, sun, and other terrestrial elements.

The origin of universe from a primeval sacrifice, in which a cosmic being offers himself as an oblation, is not known in primitive mythological traditions. However, the sacrifice of the male Purusha here is not so much the primordial sacrifice of a world giant or the type *Ur-mensch* found in Norse or Germanic mythology, as it is a cosmogonic idea based on ritual sacrifice itself as the origin of universe. (Based on *Ṛg Veda* 10.90, as cited in De Bary, 1967, p. 13.)

Third, the philosophical concept considered the beginning as an empty space with no atmosphere or sky. The universe was born out of its

own nature, possibly by its own inherent heat. The *Ṛg Veda* also attempted to provide a scientific explanation of the mystery of the origin of the universe. Accordingly, the "creation of universe has started with the origin of water and the cosmic golden egg [embryo, *Hiranyagarbh*] which very well fits in the geological and biological evolution of the earth with the water age, origin of Zoophytes, primeval fishes, reptiles, invertebrates, vertebrates, and mammals" (Tripathi, 1969, p. 3). It also said that water pervaded the whole universe which held fire in its womb. This indicates that during the Vedic age, the civilization was aware of the fact that the interior of the earth was very hot. The fire probably refers to the rising temperature beneath the surface. The importance and dominance of the water were also realized. The *Māhāpurāṇa* further crystallizes the idea that the world endures under its own nature and is divided into hell, earth and heaven.

Fourth, the instrumental origin idea is reflected in the union of heaven and earth caused by the action of different gods, such as fire (*Agni*), sun (*Sūrya*), and *Indra*. "The central idea of various cosmogonic theories of the vedic and postvedic period appears to be (1) existence of the water in the beginning, and (2) creation of the cosmic nucleus – *Prajāpati*" (Ali, 1966). *Prajāpati* is an embodiment of propagation and hence maker of universe. In this concept, they also recognize the supportless movement of the heavenly bodies as iron pieces around a magnet in the sky. Puranic literature mentions solar and lunar eclipses several times although their true mathematical theory was not known. Therefore mystical explanations were advanced.

The demon will obscure the moon and the sun at the end of the dark fortnight and the full moon. Entering the shadow of earth and moon, the swarthy-figured concealed demon will bring adversity to the moon and sun respectively (Tripathi, 1969, p. 39).

The *Upaniṣads* spoke indirectly about the spheroidicity of the earth. The description of the rising and setting sun is mentioned in *Prapathaka III*, *Khanda* 6–10 to the *Chandogya-Upaniṣad*: "So long as the Sun rises in the east and sets in

the west” (sixth *Khanda*) (Maxmueller, 1900). The concept of the rising and setting of the sun was directly related to the shape of the earth. It has been suggested that the sun’s rays did not spread over the earth at the same time, but that they fell by slow degrees, suggesting that the earth was a sphere.

Jātaka tales also mention the rising and setting sun. The whole society seemed to try to have a proper balance with the environment. They frequently referred to the laws of nature which were important for their survival.

The sun gets up each morning
(And the sun is free)
It goes to bed each night,
Why not we?
The clouds, the rain, the earth,
This very Banyan tree,
Obey the laws of nature.
So do we!”
(“The Oldest of the Three” DeRoin, 1975)

There were six seasons: *Vasanta* (spring), *Grishma* (summer), *Varsha* (rains), *Hemanta* (early fall), *Sisira* (late fall) and *Seet* (winter) are recognized in Vedic literature. Seasons are also discussed in the *Upaniṣads*, but they identified only five, as *Hemanta* and *Sisira* were merged. In the region where the *Upaniṣads* were composed (Punjab Plains) it was difficult to differentiate between the two. The year began with *Grishma* (summer) and concluded with *Vasanta* (spring). Wherever it rained sufficiently, crops were produced; this implied regional variation in rainfall. Punjab, where Aryans settled first, is drier than the east (Bihar and Bengal). With the spread of Aryan colonies from west to east, it was possible to draw a comparative picture of rainfall. The correlation between availability of rain water and food production has also been established in the ancient documents, pointing to the absence of irrigation.

The ancient literature also described the racial composition of the population and their geographical distribution. The *Rg Veda* also mentions non-Aryan tribes. It talks about *Dasyus* (Dravidians) not tamed by Aryans, who were considered civilized and supported a patriarchal family system as opposed to the Aryan

patriarchal family. The *Rg Veda* also mentions *Rakshasas* (demons), who were short, dark, thick lipped, fierce in appearance, curly haired and possibly of Negroid origin. They were considered hostile to Aryans. They did not worship fire. *Rakshasas* were engaged in guerilla warfare, attacking Aryans at night and stealing their cattle. Another tribe mentioned in the *Rg Veda* is *Paishachas*, who were ruddy in appearance.

The ancient literature discussed a cyclical human development on the earth. The Hindu view expressed in the *Laws of Manu*, speaks of four ages – *Kṛita*, *Tritā*, *Dvāpara*, and *Kali* with a sharp break at the end of each age. Physical and spiritual deterioration occurs at the completion of the 4-age period with the universe coming to an end and then beginning a new cycle. The *Laws of Manu* also stated that the age of Gods starts with the *Kṛita* (Winning Age).

In the Winning Age [*Kṛita*], religion is entire, standing on all 4 ft, and so is truth; and men do not acquire any gain through irreligion. But in the other [ages], through [such wrong] gains, religion is brought down foot by foot; and because of theft, lying and deceit, religion goes away foot by foot. In the Winning Age people are free from sickness, achieve all their goals, and [have] a lifespan of 400 years; but in the ages that begin with the age of *Treta*, their lifespan grows smaller foot by foot” (Laws of Manu, 1991).

Jainism adheres to the teachings of ► *Mahāvīra* who died in 468 B.C.E. He was a contemporary of Buddha. The Jains also believed in the cosmic cycles, but unlike Hindus they did not foresee any sharp end at the end of the periods (ages). The Jains divided a full cycle into six periods, each with ascending and descending halves. At the end of the sixth period, designated as “very wretched,” human deterioration reaches its peak with a fierce storm wiping out almost all inhabitants. After this a new six-cycle period starts.

As discussed by Tripathi, *Vrhanardiya Purāṇa* provides valuable information on mathematical geography. It gives the radius of the earth as 800 *Yojanas* or 4,000 miles (1 *Yojan* = 5 miles). The diameter was calculated as 1,600 *Yojanas*

and circumference as $1,600/10$ or $1,600 \times 3.162$ *Yojanas*. It provided a formula for calculating the circumference of any latitude parallel to the equator. These facts show that ancient Indian society was indirectly aware of geographical facts and they also made an effort to work on it scientifically (Tripathi, 1969, p. 40).

A section of *Atharva Veda* and the *Aitareya Brāhmaṇa* refers to five geographical divisions of India, which remains valid today. Further details of the divisions are given in the two great epics (*Rāmāyana* and *Mahābhārta*) and the *Purāṇas*. They contain some chapters giving a fairly good account of not only the different territorial divisions of India, but also rivers, mountains, lakes, forests, deserts, towns, countries, and people (Gupta, 1973). India, as mentioned in the *Purāṇa*, is bordered by Himavat or the Himalayas in the north and by the seas in the south, but Puranic *Bhāratvarsha* stretched from the Himalayas in the north to the Southeast Asian archipelago.

The authors of the *Purāṇa* seem to have been acquainted directly or indirectly with the major portion of India. The concept of Hell as described in the Puranic literature covers a geographical region, which is inhospitable and uninhabitable. The road leading to Hell had extreme weather conditions (arid and devoid of water), marshy and swampy land, and very dense forest infested by dangerous animals. They knew that the planet earth had regions which were not conducive for human habitation. So the importance of a favorable environment to survive was known to the people. Living in unfavorable and dull conditions was equivalent to living in "hell." The *Purāṇa* also mentioned favorable sites for human settlements. Availability of water was the decisive factor. According to Tamaskar, sites of settlements during the Puranic age were associated with escarpments, summits of mountains or hills, riverbanks, situation near lakes or tanks, islands, seacoast and forests. Riverbanks were the most important of all the sites. In addition to providing water, they also served as a means of transportation for goods and humans. Modern settlement geography also finds the wet-point-sites as the most favorable for human settlement.

Different geomorphologic features were discussed in the *Rāmāyana*, such as mountains, plateaus, disintegrated rocks, cascades and falls, caves, etc. The mighty Himalayas were divided into three regions – the outer, the lesser, and the interior conforming to the present day classification. The *Rāmāyana* indirectly deals with economic and commercial geography. It mentions the trading relations between different regions, trading items such as horses of Kāmbōja (Cambodia), silk goods and silver in the neighboring islands of Java, gold mines in the west and so on. The epic also provides information regarding prevailing weather conditions.

Mist and its disappearance through diurnal rise of temperature, mist and severe cold, cold western wind, water vapor hanging on the surface of the river, dew formation on the sandy margin of the bank and snowfall give a very good description of winter season with some of its geographic paraphernalia. Mountain winds or wind of mountain valleys are also spoken of" (Tripathi, 1969, pp. 103–104).

The *Rāmāyana* indirectly explains the hydrological cycle in its simplest form. It relates solar heating of the ocean, evaporation and cloud formation. It narrates the physical movement of people in different directions. This implies that the transportation and communication system were in a developed stage. There is mention of five types of roads – lanes (*Vithi*), streets (*Rathya*), by-roads (*Uprathya*), roads (*Mahapath*), and National Highways (*Rajmarg*) (Tripathi, 1969, p. 166).

The *Mahābhārata* gives a good account of topography, crops, people's occupations and their political and legal institutions. During that period, India had flourishing international trade with central Asia. This points to the fact that ancient Indians had enough knowledge about sea and land routes and even knew about the air circulation system and the tides. By the time of the composition of the *Mahābhārata* the idea of seven continents, each surrounded by oceans, was firmly established. Four areas are Jāmbū (all of Asia minus the east), Kuśa (Middle East), Śālamali (Eastern Africa), and Puskara (Eastern Asia). The southern part of Jāmbūdīpa was

Geography in India,

Fig. 2 Geo-political zones of Kautiliya (Modified from Tamaskar, 1985)

inhabited by Hindus in the land called Bharata or Bharatvarsha. At the center of the Jambūdhwīpa was the Meru, identified with Pamir knots, and at the northern extremity adjoining the Arctic Ocean was the Uttarakuru. Jambūdhwīpa was surrounded by an ocean, meaning a physical barrier.

Kautilaya's *Arthaśāstra* discusses the principles of territorial sovereignty and geopolitical principles. According to Kautilaya, the seven elements of the state were the king (*Swāmi*), the minister (*Amātya*), the country (*Janapada*), the fort (*Durga*), the treasury (*Kosa*), the army (*Danda*), and the ally (*Mitra*) (Knagle, 1965). *Janapada* meant both the land and the people. The organization of space also extended into the coastal regions and territorial waters. Kautilaya believed that success of any state depended on peace which could be affected by the internal and external forces reflecting centripetal and centrifugal forces of modern political geography, discouraging disintegration and encouraging integration of the state. Kautilaya's sixfold policy dealt with the internal and external problems of the state directly, and the policy revolved around peace, war, preparation for war, neutrality,

seeking shelter and dual political policies. On the basis of political attitudes the neighboring states at the periphery or beyond were conceived as geopolitical zones of enemy, friend, enemy's friend, friend's friend, or friend of enemy's friend with increasing distance (Fig. 2).

According to Kautilaya, "place means earth. In that the region of the sovereign ruler extends northwards between Himavat and the sea, 1,000 yojanas in extent" (Tamaskar, 1985, p. 96). This implies that the natural boundaries for the states were considered important. The right location of the capital within the boundary manifested geographical consideration. Kautilaya emphasized the importance of the strategic location of the capital.

...The king may have his fortified capital, as the seat of his sovereignty (*Somudayasthanam*) in the center of his kingdom in a locality naturally best fitted for the purpose, such as the bank of the confluence of the rivers, a deep pool perennial water, or of a lake or a tank, a fort, a circular, rectangular or square in form, surrounded with an artificial canal of water, and connected with both land and water paths. (Knagle, 1965)

The *Arthaśāstra* also mentioned the importance of developing means of transportation and

communication in order to have political unity within the state. Developed transportation would serve as channels for the army to reach at a time of crisis. In addition to defense it would also help to promote trade and commerce, serving as a lifeline for the state.

The great verse writer, Kalidasa, (designated the “Shakespeare of India”), created *Meghadūtam* and *Raghuvamśa*. They showed a detailed knowledge of hills, rivers, plains, and cities. In *Meghadūtam*, Kalidasa’s description of the path from Ramagiri to the Himalayan gate in the poetry is no less than a geographer’s account. While sending clouds as messengers, the routes, rivers, hills, and cities lying on the way were described. Again, in *Raghuvamśa*, the poet showed in-depth knowledge of Indian geography. The kingdoms as described by Kalidasa show that he had some knowledge of the southern countries of Pandya and Kerala.

Greeks and Persians are the earliest foreign people to leave accounts of India. Greek writings indicate that ancient Indians had knowledge of the shape and size of their country. In 320 B.C.E., Eratosthenes gave India the shape of a rhomboid or unequal quadrilateral which had Indus on the west, the mountains on the north and the sea on the east and south. In 300 B.C.E., Megasthenes, a Greek ambassador of Seleucus Nicator, visited the court of a north Indian King, Chandragupta, and left an account of India on his return. In the *Mahābhārata*, India is described as an equilateral triangle divided into four smaller equal triangles. The apex of the triangle was Cape Comorin and the base was the Himalayas. Cunningham drew a small equilateral triangle by drawing a line between Dwarka (Gujarat) and Ganjam (Orissa) and repeated the exercise on each of the three sides to obtain four divisions of India in one large equilateral triangle. ► [Varāhamihira](#) identified eight divisions. The central division of Pañchāla (Punjab/Haryana) was surrounded by Maghada (east), Kalinga (southeast), Avanta (south), Sindhu-Sauvīra (west), Anarta (southwest), Madra (further south) and Kauṇḍa (northeast).

In the world map of Ptolemy (second century A.D.), a Greco-Egyptian geographer-astronomer,

the true shape of India was distorted. He ignored the southern peninsula and drew an almost straight line from the Gangetic delta to the Makran coast in Baluchistan.

The cause of this mistake is partly due to the erroneous value of 500, instead of 600, Olympic stadia, which Ptolemy assigned to an equatorial degree, partly to an overestimate in converting the road distance into map measurement, but chiefly to the excess which he allowed for the distances of land journeys over those of sea voyages” (Cunningham, 1979).

Though only the southern part of Jambūdīpa was considered Bhāratavarsha, the Indians referred to the latter as the whole earth because the landmass of South Asia surrounded by mountains in the north and seas in the south was not only a physical cul-de-sac, secluded from other people, but was so productive and large that to the people of India it constituted the world. Puranic legend claims that King Bhārata, whose name was identified with the country (Bhāratavarsha), ruled the entire earth, meaning all of India. Such was the case with the emperor Aśoka as inscribed in his Fifth Rock Edict declaring that he was ruler of the world.

During the ancient Indian historical period when the country was shedding its narrow tribal characteristics, turning into a consolidated tribal conglomerate of Aryavārta (land of the Aryans), converging into organized states, no systematic study of geography evolved. On the contrary, during the same period, the Greeks and the Romans explored the geographical features of their known and unknown worlds and provided the basis for modern geography.

Geography in Mesoamerica

Vincent Herschel Malmström

Unlike the ancient Greeks, for whom all knowledge could be categorized according to a tripartite classification – the phenomenon itself, its place in time (history), and its place in space (geography) – the civilizations of pre-Columbian Mesoamerica viewed all knowledge as religion, some aspects of which found their reflection both in time and space. The most original intellectual creation to emanate from Mesoamerica was the 260-day sacred almanac, known variously as the *tzolkin* among the Maya and as the *tonalpohualli* among the Aztecs. Pre-dating the 365-day secular

calendar, which these people also developed, it ran concurrently with the latter to produce a never-ending series of 52-year cycles ($365 \times 52 = 260 \times 73 = 18,980$ days), giving rise to the Mesoamerican belief that history repeated itself every 52 years.

Though the origin of the 260-day calendar has long been debated, the most convincing explanation for its astronomic underpinnings was first given by Zelia Nuttall in 1928, who argued that it represented the interval between zenithal sun positions at Copán, the major Maya astronomical center located in the mountains of western Honduras. At the latitude of Copán (14.8°N.), the sun passes overhead at noon on August 13 on its apparent southward journey to the Tropic of Capricorn and again on April 30 on its apparent northward journey to the Tropic of Cancer. In 1945, Merrill called attention to the “coincidence” of the August 13 date with the start of the so-called Maya ► [Long Count](#), which in the Goodman-Martínez-Thompson correlation between the Maya and Christian calendars fixes the beginning of the present cycle of the world as August 13, 3114 BCE. (The Long Count represented a meshing of the 260-day sacred almanac and the 365-day secular calendar in such a way that each day was as uniquely and precisely identified as they are in the Julian Day system employed by modern astronomers.) In 1948 a Guatemalan scholar, Girard, contended that the calendar’s birthplace lay along the same parallel of latitude but in the mountains of his country instead. While concurring in the astronomical importance of the 14.8° parallel of latitude, the present writer was forced to reject both Copán and the highlands of Guatemala as the calendar’s cradle, for reasons both of history and of geography. No pre-Columbian site situated along that parallel in the highlands of Central America predates the fifth century AD, whereas the sacred calendar is known to have been in use for several centuries BCE. Furthermore, many of the day-names used in the sacred almanac commemorate lowland tropical animals. The only place where the requisite astronomy, history, and geography come together is at Izapa, on the Pacific coastal plain of Mexico, where a large

Geography in Mesoamerica, Fig. 1 Both Izapa and Copán are situated just south of the 15th parallel of North latitude, the former immediately adjacent to the

boundary between Mexico and Guatemala and the latter in the mountains of western Honduras (Map by the author)

ceremonial center of Formative age (1500 BCE-300 AD) is found amidst a tropical rainforest ecological niche (Fig. 1).

Field work at Izapa in 1974 not only revealed that the entire ceremonial center is oriented to Tacaná, a commanding volcano of 13,428 ft elevation on the northern horizon but also that the highest volcano in Central America, Tajumulco (13,845') marks the azimuth of the rising sun on the summer solstice (June 22) as seen from Izapa (Fig. 2).

This use of prominent topographic features to serve as calendrical markers was subsequently traced to the oldest so-called Olmec ceremonial centers of San Lorenzo (1200 BCE, oriented to Zempoaltepec (11,138') at the winter solstice sunset), La Venta (1000 BCE, oriented to Cerro Santa Martha (4,600') at the summer solstice sunset), and Tres Zapotes (800 BCE, oriented to Cerro San Martín (4,600') at the summer solstice sunrise), but also to the earliest ceremonial centers of the Mexican plateau, including Cholula, Cuicuilco, Tlatilco, and Tlapacoya (Fig. 3).

Significantly, only two of the earliest Maya sites, Uaxactun and Tikal, have mountains within view, but both of them are likewise oriented to the winter solstice sunrise over the highest peak within sight – the first to Baldy Beacon (3,346') and the second to Victoria Peak (3,680'). In each instance, the local site-factor which pinpointed the ceremonial center's location was the availability of water, both for domestic uses and, in the early Olmec centers, for transport, but only when the situational factor of the proper solstitial orientation coincided with it (Fig. 4).

Interestingly, where prominent mountains are not visible on the horizon, the early Mesoamericans substituted architectural alignments for solstitial orientations. The greatest of pre-Columbian cities, Teotihuacán, about 30 miles northeast of present-day Mexico City, combines an intriguing blend of both principles: it is located precisely in line with the winter solstice sunrise over the highest mountain in Mexico – Citlaltépetl, or Orizaba, 18,700' – but the peak itself is obscured by a low ridge of hills on the southeastern horizon. It would appear that

Geography in Mesoamerica, Fig. 2 The unique geographic position of Izapa permitted its priests to calibrate precisely both the length of the 260-day sacred almanac and the 365-day secular calendar – the first by zenithal passages of the sun and the second by measuring the

interval between summer solstice sunrises over Central America's loftiest volcano. The sacred almanac had its beginnings about 1320 BCE and the secular calendar was initiated some 34 years later (Map by the author)

Geography in Mesoamerica, Fig. 3 Throughout the areas they occupied in present-day Guatemala, El Salvador, and Mexico, the Olmecs continued the precedent of orienting a ceremonial center to a solstitial sunrise or sunset, begun at Izapa. On this and subsequent figures,

lines in orange indicate solstitial orientations while those in red mark orientations to the August 13 sunset. Here we see the orientations found at the oldest Olmec sites in southern Veracruz state (Map by the author)

Geography in Mesoamerica, Fig. 4 The flat and relatively featureless peninsula of Yucatán provided the lowland Maya with no mountains with which they could locally calibrate the calendars they had inherited from the Olmecs. However, once within sight of the Maya

Mountains of present-day Belize, the practice was revived at two of their most ancient and important sites in the Petén region of Guatemala, Uaxactun, and Tikal (Map by the author)

a “relay station” was built there to allow the priests of Teotihuacán to calibrate their calendar with the southernmost position of the sun, whereas the entire city itself was meticulously gridded to the sunset position on August 13 – the day the present cycle of the world was believed to have begun (Figs. 5 and 6).

The commemoration of the August 13 sunset is also found in the layout of other ceremonial centers on the Mexican plateau of later, Toltec vintage, but its most widespread use in city planning was amongst the Maya. The location of the earliest Maya ceremonial center at Edzná (dating to 150 BCE) was primarily dictated by the presence of the largest Aguada, or temporary lake, in all of the Yucatán, but its internal layout clearly reflects their religious preoccupation with the August 13 sunset. Similarly, numerous structures throughout the Maya regions of Yucatán and Petén reflect the August 13 alignment, among them the Codz Pop at Kabah, the Pyramid of the Magician at Uxmal, and El Caracol at Chichén

Itzá, to name but a few. The crowning blend of celestial mechanics, time, and space is to be found in the Maya capital of Tikal, where five sky-scraper pyramids, all about 200 ft in height and all constructed in the eighth century, mark the alignments of the August 13 sunset (Temple I to Temple IV), the equinoxes (sunrise Temple III to Temple I; sunset Temple I to Temple III), and the winter solstice sunrise (Temple IV to Temple III) in a sophisticated astronomical matrix. Further, an alignment from Temple V to Temple I not only marks a perfect right angle to the August 13 alignment but one from Temple V to Temple II likewise pinpoints the westernmost point in the rotation of Polaris, which at that time was the closest thing to a polestar which existed, even though it was a full 8° away from its present position (Fig. 7). (Clearly, the repeated use in Mesoamerican ceremonial centers of the August 13 sunset orientation not only forcefully argues for the sacred almanac’s astronomical origin but it also makes any alternative explanation, such as

Geography in Mesoamerica, Fig. 5 As the Olmecs carried their calendrical systems onto the plateau of Mexico, they found a plethora of great volcanoes to which they could orient their incipient ceremonial centers. Following the destruction of Cuicuilco about 150 BCE, they founded

what was to become the largest urban center in the New World at Teotihuacán and ensured that it was solstitially oriented to Orizaba, the highest mountain in Mexico (Map by the author)

Geography in Mesoamerica, Fig. 6 At least three key astronomical concepts are built into the layout of Teotihuacán, Mesoamerica's greatest pre-Columbian metropolis. Not only it is oriented to the winter solstice sunrise over the highest mountain in Mexico, but its entire internal structure is also aligned to the sunset position on

August 13. Furthermore, the location of the Pyramid of the Moon and the Pyramid of the Sun, its two most imposing architectural features, precisely defines the meridian, enabling both noon and midnight to be calibrated as well (Photo by author)

Geography in Mesoamerica, Fig. 7 At Tikal, sometimes called “the capital of the Maya,” the planning and construction of five “skyscraper” pyramids, all carried out within about a 50 year period in the late eighth century,

pointedly demonstrates how the Maya combined the spatial arrangement of their architectural structures with key temporal “landmarks” in their religious year (Map by the author)

the length of the human gestation period or the simple permutation of the numbers 13 and 20, untenable.)

In the fifth century, the Mesoamericans appear to have carried out two remarkable geographic expeditions. Although they both had ultimate religious goals in mind, these endeavors probably reflected the closest approach the pre-Columbian civilizations ever made to what we regard as scientific inquiry. The priests of Teotihuacán dispatched an expedition into the northern desert to determine where the “sun stopped” in its annual migration, and in consequence of this, the astronomical center of Chalchihuites was founded on the Tropic of Cancer. Lacking a better means of recording key alignments, they dug trenches through the earth and plastered them with adobe to mark the summer solstice sunrise. (In the tenth century the Toltecs added a trench to mark the beginning of their New Year, February 12.) Perhaps under Teotihuacán’s sponsorship, the Maya carried out a similar expedition at about the same time to locate the place where the 260-day sacred almanac could be calibrated. The result of this venture was the founding of Copán, in the western mountains of Honduras, whose oldest recorded ► [Long Count](#) date is 435 AD. Thanks to its key geographic location, Copán was ultimately to become the Mayas’

principal center for astronomic studies – the late and distant heir of Izapa where the first intellectual stirrings had begun nearly two millennia earlier.

Geography in the Islamic World

Amriah Buang

National University of Malaysia, Bangi Selangor, Malaysia

Geography is the study of the Earth's surface as the space within which the human population lives. The internal logic of this study has tended to split modern geography into two parts: physical and human. Such a division was inapplicable in the geography of the Middle Ages, the golden age of scientific inquiry in Islamic civilization (Tozer, 1964). Nevertheless, if we confine the meaning of science and technology to the natural and exact sciences, then a survey of geography in Islam may be divided into three categories: exploration and navigation, physical geography, and cartography and mathematical geography.

Prompted by the sense of Islamic brotherhood, and the quest for knowledge and piety, Muslim scholars engaged in many exploration and navigational activities between the ninth and twelfth centuries (Nafis, 1972). The journeys were not confined to the political boundaries of the Islamic empire but extended to distant regions such as China, Southeast Asia, Southern Africa, and Russia. In Northern Europe, the extent of the Muslims' travels may be gauged from the fact that some ten million pieces of the Islamic state's coins have been found around the Baltic. In Sweden alone 12,000 such coins were discovered at 169 sites.

From extant documents, it may be deduced that no less than 20 geographers were involved in navigation and exploration, resulting in a massive store of information and descriptions of the terra-cognita. Out of these, five may be regarded as outstanding. These geographers are al-Muqaddasī (b. tenth century), Ibn Jubayr (b. AD 1145), Yāqūt (b. AD 1179), Ibn Baṭṭūṭa (b. AD 1304), and Ibn Mājid (b. AD 1400). The contributions of Ibn Faḍlān (tenth century), Ibn Hawqal (tenth century), Mas'ūdī (d. AD 456), al-Bīrūnī (b. AD 972), al-Idrīsī (b. AD 1099), Ibn Rushd (AD 1300), Jawainī (ca. AD 1000), Abdur

Razzāq (AD 1000), Ya'qūbī (d. AD 897), al-Marwazī (d. AD 887), Nāṣir-i-Khusraw (b. AD 1003), al-Māzinī (b. AD 1080), al-Maghribī (d. AD 1274), and Ibn Khurdādhbih (ca. AD 900) are also noteworthy.

Al-Muqaddasī or al-Maqdisī spent 20 years travelling the length and breadth of the Islamic empire. He perceived that it was important to be able to substitute hearsay with personal observations and set out on a series of field trips to gather information and knowledge about places. One of his major works was *Kitāb aḥsan al-taqāsim fī ma'rifat al-aqālīm* (The Best Climatic Divisions), which was regarded as accurately informative of areal differences in climate in the Islamic world. Ibn Jubayr was meticulous in his description of places such as Mecca and Medina in his *The Travels of Ibn Jubayr*, which became a basis for historical comparison with later writings. Yāqūt's *Mu'jam al-buldān* (Dictionary of Geography) was another major contribution, and his extensive travelling within the Islamic empire resulted in a vivid account of the Islamic world before its fall to the Mongols. Ibn Baṭṭūṭa certainly stands out as the most seasoned traveller. In 20 years he journeyed as far as 120,675 km (75,000 mile) covering countries like China, Southern Ukraine, Sumatra, the Malay Peninsula, Kampuchea, Maldives, and the Volga. His detailed accounts of life in these places contributed further to the geographical preoccupation with different areas. However, Ibn Mājid and Sulaymān al-Mahrī were better informed about the Southeast regions of the world. The former's *Kitāb al-fawā'id fī uṣūl 'ilm al-baḥr wa'l-qawā'id* (Principles of Navigation) and the latter's *'Umda and Minhāj* became important references for those who wanted firsthand information on the Malay Archipelago (Tibbets, 1979).

The fact that collectively the Muslim travellers and navigators covered more than two-thirds of the Earth's surface illustrates the Muslim scholars' disdain for armchair scholarship. That distant places were visited for collecting information at a time when vehicles, vessels, and instruments were underdeveloped, and when both land and sea routes were more unsafe than otherwise, serves to prove the inquiring spirit of the Muslim geographers.

In physical geography the contributions made by Muslim geographers in the Middle Ages pertain to their theoretical speculations about the lithosphere, atmosphere, hydrosphere, and biosphere (Arnold, 1926). In cosmology, they came out with new notions regarding the relationship between cosmological cycles and geographic changes. For instance, the Sincere Brotherhood or Brethren of Purity (*Ikhwān al-ṣafā*), an association of scholars whose treatises were considered the standard for scientific knowledge of their day, conceived of the influence of the angle of declination on insolation, the influence of relief on precipitation, and the relationship of precipitation with the origin of streams and springs.

With regard to the lithosphere, the solid part of the Earth, Muslim geographers thought of landforms as being the results of erosion, deposition, and tectonic activities. Soils were considered the results of organic decomposition, and winds (gases in modern usage) trapped underground and seeking outlets were held responsible for earthquakes.

Their theories on atmosphere embraced both local atmospheric phenomena and the distribution of macro-climatic elements. Thus, by envisaging atmospheric processes, such as insolation, convection, and evaporation, they were able to account for the formation of clouds, rainfall, snow, fog, and dew as different forms of evaporation due to differences in temperatures. They also divided the world into three climatic zones: hot, cold, and temperate, based on their understanding of the changing positioning of the sun.

In terms of the hydrosphere, most of the Muslim geographers' works were focused on understanding the causes of tides and the origin of oceans and reasons for their salinity. In accounting for tides, the geographers were divided. Some pointed to the influence of heat generated by the sun and moon; others attributed the tides to the influence of wind on the movement of sea water. Muslim geographers, in general, concurred with their Greek counterparts in thinking the oceans had originated from the remnants of primitive precipitation which did not get dried when matter was formed in the universe. They, however,

differed again with respect to marine salinity. Some ascribed it to the transformation of calm water to salty hard water after prolonged gestation.

Regarding the biosphere, geography in the Islamic Middle Ages saw the categorization of flora and fauna according to the grade of their creation. Thus, al-Jāhīz wrote four classes of animals based on their locomotion: those that creep, walk, swim, and fly.

By contrast, Ibn Maskwaih's division was based on the creatures' stage of evolution, with the lowest stage being occupied by vegetation which did not require seeds to grow and humans occupying the highest stage of evolution. The categorization by the *Ikhwān al-ṣafā* was based on senses, whereby creatures with one sense occupied the lowest level and those with five senses the highest. In spite of these differences, the Muslim biogeographers agreed that the spatial distribution of organisms was governed by climate, topography, and soils.

Yaq'ūbī was noted for his *Kitāb al-buldān* (The Book of Countries) written in AD 891, in which he described in detail the physical characteristics of Baghdad, Samarra, Iran, Turan, and the present Afghanistan. Ibn Rustah discussed the importance of locational and physical environmental factors on the development of cities, such as Medina and Mecca, in the seventh volume of his *al-A'lāq al-naḥṣah* (The Book of Precious Things), an encyclopedia completed in AD 903. Al-Maqdisī described an imperfect spherical Earth, the northern hemisphere of which contained more land than water. He also gave a detailed account of the world climate in terms of zones. Yet the most daring speculation may be ascribed to al-Bīrūnī, who theorized that, based on empirical evidence of its physical environment, the Indian subcontinent might have been a continental shelf before depositions raised it into a landmass. Lastly, al-Qazwīnī (b. AD 1203) produced two books: *'Ajā'ib al-buldān* (The Wonders of the Lands or Geography) and *'Ajā'ib al-makhlūqāt* (The Wonders of Creation or Cosmology), which were notable for their reference to more than 50 authors. The significance of this fact is that the large number of practicing geographers that were cited indicates how active

and prolific physical geography was in the medieval Islamic civilization.

The achievement of Muslim geographers in mathematical geography may be described in various phases of development (Alavi, 1966). An important phase was the establishment of the school of mathematical geography in Shiraz, Persia, after AD 950. This school produced important scholars such as 'Abd al Raḥmān al-Ṣūfī and Ibn al-A'lam. 'Abd al Raḥmān reviewed Ptolemy's *Star Catalogue*, while Ibn al-A'lam compiled an astronomical table which became a main source of reference for centuries. Important developments took place in the school in Cairo toward the end of the tenth century and the early eleventh century. Important scholars from this school included Ibn Yūnus, who prepared astronomical tables and corrected several errors committed by the Greeks Ptolemy and Hipparchus. For instance, according to Ptolemy, the precession of equinoxes occurs at 1° in 100 years, but the correct measure was 1° in 70 years, as calculated by Ibn Yūnus. His book entitled *Al-zīj al-ḥakīmī* (Tables of Wisdom) explained, among other mathematical ideas, the method of calculating longitudes and latitudes.

Among the notable works written in Central Asia of this school was al-Bīrūnī's book entitled *Taḥdīd nihāyāt alamākin* (The Determination of the Coordinates of Cities). Other scholars of high reputation were al-Zarqāllu, Naṣāl-Dīn al-Ṭūsī, and Ulugh Beg. Al-Zarqāllu produced several books on astronomy including the *Toledan Tables*. His other work, entitled *Qānūn* (Canon), was used by European scholars during the Renaissance. Al-Ṭūsī is remembered for his book *Zīj-i-īlkhānī*, which recorded all the notes and observations he made from the observatory of Maragha. His other important writing was on the astrolabe and the problems related to the measurement of time, celestial altitudes, meridians, and the like (Kennedy & Kennedy, 1987). Ulugh Beg was a Tartar prince (AD 1393–1449) who was also noted for the observations he conducted from the observatory in Samarkand. He managed to point out several errors committed by Ptolemy in the latter's tables and made new tables of latitudes and longitudes.

With respect to cartography, Muslim scholars followed two schools: one was based on the cartographical method of Ptolemy and the other on that pioneered by al-Balkhī. Ptolemy's teachings were followed by al-Idrīsī, and al-Balkhī's were continued by al-Istakhrī, Ibn Ḥawqal, and al-Maqdisī. The Muslims' maps were drawn and utilized in conjunction with countries and regions. Idrīsī became famous in the West because of his maps and cartographical work. His maps were valued not so much because of their accuracy but because of the symbols he used to distinguish various physical and cultural forms.

A prominent feature of the achievement of Muslim scholars in mathematical geography and cartography was the invention of scientific instruments of measurement. Among these were the *astrolab* (astrolabe), the *rubā* (quadrant), the gnomon, the celestial sphere, the sundial, and the compass. The portable astrolabe was used by navigators for measuring altitudes up to the seventeenth century. The rubā was used for measuring the value of angles. The gnomon was also used for measuring altitudes of the sun and other planets. The use of celestial sphere was to explain celestial movements, the sundial for calculating daily time and the azimuth (compass bearing) of Mecca, and the compass for finding direction during navigation. In human geography the achievement of Muslim geographers during the Middle Ages may be summarized into two main categories: (1) works which attempt to explain factors deemed responsible for influencing, or even determining the traits, characteristics or qualitative nature of a population or community, and (2) works which describe basic facts (social, economic, political, and cultural aspects) about a society's or a community's life. Viewed from the perspective of contemporary modern human geography, some of these works coincide with discourses on environmental determinism (the doctrine that human activities are controlled by the environment) and environmental possibilism (the view that the physical environment provides the opportunity for a range of possible responses and that people have considerable discretion to choose between them) (Institut für Geschichte der Arabisch-Islamischen Wissenschaften, 1992). Others may

be aligned more with traditional regional geography which was heavy in chorography (the study of the areal differentiation of the Earth's surface, i.e., the areal variation of human and physical phenomena as they relate to other spatially proximate and causally linked phenomena) or idiography (a concern with the unique and the particular). Some of the names identifiable with this episode of Islamic human geography were Al-Masudi – for his explication as to how climates differentiate between people of northern and southern hemispheres – and Al-Maqdisi, for his characterization of settlements based on the temperament of their inhabitants.

Modern human geography has since been dominated by thoughts and works of Western human geographers. So much has happened to the secular epistemological thinking of this subdiscipline of geography, and an Islamic preliminary review of it was written by Buang (1992) followed by an outlining of the content of the Islamic perspective by the same author (Buang, 1996). The latter further pursued the cause of the Islamic perspective of contemporary human geography with a paper which attempts to persuade secular mainstream human geography, on the platform of postcolonial studies, to engage epistemologically with the Islamic perspective. Whether acknowledged by the West or not, an Islamic epistemology exists for both natural and human sciences. And since advancing postcolonial geography must also include the decolonization of knowledge, it is timely to consider if an alternate, Islamic human geography has instructive worth with respect to mainstream human geography. This entry sketches a broad outline of an Islamic human geography and shows how it (i) addresses some of the fundamental epistemological questions non-Islamic, largely secularized, geographies of the West have abandoned or silenced; (ii) incorporates a number of ideas within mainstream human geography; and (iii) outlines novel frameworks for synthesizing differences that trouble mainstream human geography. While the showcasing of Islamic geography may not alter its irrelevance to secular and non-Islamic geographies, its illumination confirms its relevance to Muslim

contexts and, by refraction, the situated nature of mainstream human geography. As such, this exploration serves the purpose of opening out the kind of conversation across differences that postcolonialism seeks to advance (Buang, 2013).

Geography of the Native North Americans

Martha L. Henderson

Native North Americans sustain sophisticated and complex cultures. What native peoples say about themselves with their own constructs of

space and place is essential to understanding native North American populations. This essay attempts to describe geographical data including native spatial organization, relationships with the natural environment, and the location and significance of places. These data and their analysis can shed light on native identity, problems of intercultural relations from a geographic perspective, and the contemporary context of native geography within the pluralistic federal states of Canada and the United States.

North American natives, those living north of the Mexican-United States border, were divided regionally by specific cultural patterns and practices such as language, religion, and relationships with the natural world. Oral traditions and material artifacts about past events provide clues to a native North America. Similar culture groups established territorial boundaries that served to strengthen group identity. Porous boundaries allowed for fluid contact between groups when conditions required. Territories generally conformed to major ecosystems of the continent.

North American ecosystems are roughly divided by landform and vegetation that include a direct reference to climatic conditions of the modern period. The subtropical Southeast extends from the center of the continent at approximately 100° West to the Atlantic coast to its northern limit at approximate 35° North. Corresponding to the west is the Southern Great Plains, Southern Rocky Mountains, and the desert Southwest. Between 35° and approximately 50° North is the temperate zone. In the west, this zone includes the rainy coastal mountain ranges of the Pacific, the cold Rocky Mountains, the dry Central and Northern Great Plains, and the humid Northeast Atlantic region. North of the temperate zone climatic conditions are generally cooler. The northern region was drastically affected by continental glaciations. Except for the Northern Rocky Mountains that extend into Alaska, the northern region has been heavily eroded and generally flattened. Very large lakes and river drainages cut across the rocky surface. Soil development is slowed due to cold temperatures. Trees rarely grow above 55° North. These

basic environmental conditions set the framework for native population habitation of the land mass (World Atlas).

Today, the international boundary between Canada and the United States divides federally recognized tribes but not self-identified culture groups. Historic treaty-making and reservation assignments create a federal geography while native populations recognize a cultural geography that reaffirms a traditional past, present, and future in Indian Country.

Traditional Native Geography

Native geography can be described on the basis of creation stories, location, territoriality and boundary making, resource adaptation and interaction with the physical environment, and place-making. Native-land relations are primarily structured around a set of beliefs that recognize Earth as the spiritual and material center of life. Generally, Natives do not divide their world between the real and the spiritual. The world includes every existing entity and those spirits who occupy them. All aspects of nature are sacred; there is no separation between the universal and human actions. For example, the Ojibway of the Upper Great Lakes region view Earth as "spirit garden." Resource adaptation and cultural patterns are closely linked, one sustaining the other. Spiritual, cultural, and physical collaboration established a balance that supported native populations in sustainable, traditional patterns.

Places usually recognize the spiritual integrity of natural objects or events that magnify the wishes of a creator. The Hopi of the American Southwest named each of their mesa homelands with respect to physical features and conditions of Hopi creation beliefs. Hopi place names not only imply the physical, but also the spiritual conditions of existence. Prior to contact with non-Hopi groups, especially non-Indian groups, each mesa was a world unto itself, anchored in a spiritual and material existence. Recent events within Hopi mesas, such as surface coal

mining by western industrialists, have wounded this sacred ground.

The White Mountain Apache maintained an oral history by telling each other about specific places. Specific places in traditional territory evoked significant events, lessons of survival, life passages, and mystical events. Without these places, the traditional history of the Apache did not occur. The power associated with each place captures the power of place within many native culture groups (Basso, 1996).

Creation Stories

The native populations of the Western Hemisphere constituted a major portion of Earth's human populations prior to European contact during a period of time generally recognized by scholars during the fifteenth century. It is estimated that populations in Central and North America could have been as high as ten million with the same amount in South America. The extent of nonnative knowledge about human habitation in other parts of the world is speculative. It is apparent in some oral traditions that natives knew of white visitors to the Americas prior to the temporal divide of the 1400s.

Northern American natives believe, and continue to believe in, creation stories that do not include a Beringia migration during periods of colder climatic conditions. Recent discoveries in North America of pre-Paleolithic skeletal remains and artifacts stimulate a growing awareness that native occupation is part of a much longer legacy of continental occupation. Native American artifacts have been found across the North American continent in such quantities as to suggest that all parts of the land mass were occupied at the close of the last major glacial period. The post-Pleistocene period is a convenient but tentative temporal divide. Contemporary native peoples are reasserting their own stories of origin, culture, language, and environmental ethics that reset the balance of authority between native peoples, federal governments, and academic researchers.

Location, Territoriality, and Cultural Boundaries

Within each major group were specific groups who established their location around specific physical features at a density that allowed a sustainable population to exist within the entire ecosystem. Local shifts in location, resource acquisition, sacred sites, and interaction zones between groups were not uncommon. These shifts were sanctioned by mutual consent although peaceful readjustments were not always the case. Major stresses such as prolonged drought or loss of a major resource caused location changes and readaptation across ecosystem boundaries.

Natives generally view area based on concepts of territoriality. Territoriality is a common recognition of a physical landscape that supports loosely allied group needs. Acute observation skills, familiarity with local and regional physical characteristics, and recognition of other social groups within the area are consistent attributes of native geography. For example, the Apache utilized an area of the American Southwest generally between the Rio Grande River and the Great Plains. Primarily a mountain people dependent on species found at various elevations during changing seasons, the Mescalero Apache also developed hunting skills that allowed them to take advantage of grasslands species such as buffalo. They shared buffalo hunting with distant Apache relatives. These other Apache groups were permitted to hunt and gather resources in the Mescalero mountain territory when grasslands resources were scarce. The Mescalero Apache held all resources as a common good to be shared when other Apache required assistance.

An important aspect of territoriality is the ability to communicate conditions of space and place. The Inuit are superb cartographers, able to produce maps of territory with accurate scale, a system of symbols, and direction. The maps also convey a sense of space and place where value is placed on animal trails, natural features, and settlement locations. An Inuit map of the north therefore demonstrates Inuit reality as opposed to another culture's maps of northern places.

The continental context of native occupation was well known to native peoples. Means of transportation and navigation technologies existed that allowed for transcontinental exchange as well as regional interaction between groups. Regionally, large game hunting and other resource-sharing opportunities allowed for contact and exchange between groups. Finally, small groups who occupied specific areas achieved a balance between resources and population needs. Expertise in the maximum utilization of all resources supported native populations within a context of spiritual, cultural, and physical balance.

Resource Adaptation

The map of traditional native North America includes recognized areas of group occupation, fluid and sometimes shifting boundaries between groups, and cultural indicators that promoted group identity and survival. Groups of similar culture and subsistence patterns are recognized within each of the major ecosystems of North America. Each major group had unique linguistic, religious, and subsistence patterns. Within each ecosystem were specific groups who maintained their own identity while recognizing their commonalities with similar groups within the ecosystem. Native populations are generally divided into the following large groups: Mississippi temple-mound builders; eastern woodlands hunter-gatherers and cultivators; plains bison hunters; southwest Anasazi; desert hunter-gatherers; west coast foragers, hunters, and fishers; plateau fishers and hunter-gatherers; sub-Arctic forest hunter-gatherers; Arctic marine mammal hunters; and island fishers (Carnegie Museum).

The use of natural resources for survival is generally framed within the context of small Indian populations, exploitation to meet needs, and returning something to nature for the use of an item. Native Americans developed a resource use paradigm that focused on the unity of all beings and their systemic value rather than individual worth. For example, individual animals within a forest ecosystem were recognized in relationship to other plants, soil, water, and air. The

use of a specific animal was always observed with respect to other elements of the ecosystem with an attitude of thankfulness and recognition of the animal as a gift. Reliance upon specific species developed over centuries of adaptation. As native groups entered new areas of North America and as North American physical environments were transformed by primarily climatic events, groups had to adjust, migrate, or face decline.

This is not to suggest that specific species were not singularly important to American Indian groups. The buffalo provided nearly all of the needs of plains bison hunters while west coast fishers relied heavily but not exclusively upon salmon. Given the low population numbers of natives, neither species were threatened with extinction due to overkill. It is reasonable to believe that resource demands and human populations would have remained static if European explorers with different technologies and valued resources had not impacted native culture groups (Native North America).

Perhaps the most striking of examples of native cohabitation is found in the cold deserts of the plateau fishers and hunters and gatherers, and the Arctic marine mammal hunters. Using simple technological devices, native peoples occupied and survived in both areas. The Piute established their primary homes along pluvial spring-fed lakes that survived continental warming. These people developed fishing and hunting technologies that allowed them to utilize birds, animals, and fish that inhabited the lakes and marshes of the Great Basin. While large game animals are scarce in the region, small animals such as antelope and rabbits were easily trapped. Plants, whose life cycles were well known to local Piute groups, were readily available. These food resources were abundant to the point that it is estimated that the Piute had more time available for leisure and social activities than any other native group.

Similarly, Eskimo experienced a high amount of time available for artist expression and social activities because they developed sufficient technologies and skills to maintain caloric intake and clothing needs. The Arctic is one of the richest animal and fish ecosystems on Earth. Native

fishing, watercraft, celestial navigation, and clothing technologies allowed the Inuit and Eskimo to thrive in the high latitudes.

Oral traditions and present practices indicate that management techniques were utilized to create and sustain certain types of ecosystems. Native use of fire to maintain open fields is apparent across the continent. Native burning may also be the primary force that created the grassland ecosystems of the mid-continent. The eastern woodland natives such as the Iroquois practiced burning of areas, known by European settlers as “old fields,” to maintain open areas for large game hunting.

Native cultural ecology places a high degree of respect for living with environmental conditions. The mental constructs of discovery and contact by Europeans overlooked the brilliance of native populations who had, through experimentation and accident, come to live in a state of balance with the physical environment. This balance was radically changed with the permanent migration of Europeans to North America.

Historic Geographies: Cultural Conflict and Emergent Identities

European influences in native North America are generally recognized as beginning in the fifteenth century with earlier contact periods a probability based on archaeological data. Contact between natives and Europeans resulted in major shifts in native geography. European tools, technologies, diseases, and interruption of traditional patterns of resource acquisition and spatial organization altered those natives who experienced direct contact. More importantly, the changes spread within the native population to affect large groups of natives who did not experience direct contact. The presence of English, French, and Scandinavian explorers and their patterns of living spread quickly from the eastern coastal areas inland. Similarly, natives living in the southwest were affected by the presence of Spanish explorers in Central America. The diffusion of European goods, ideas, technologies, and diseases spread quickly across the entire continent.

Once European settlements were established, their demand for resources had an immediate effect on the location and territoriality of native groups. For example, as French fur traders moved into the Great Lakes region, northern Algonquian peoples moved westward into Ojibwa territory. The Ojibwa peoples moved westward into Sioux territory west of Lake Superior. This migration resulted in conflict and warfare between the two native peoples. Eventually the Sioux moved further west and established themselves on the northern Great Plains. When American ethnographers described the Sioux, they called them Plains people who had adapted to living off buffalo, yet this was a very recent location and adaptation for the Sioux.

Spanish *entradas* into the southwest also created a chain reaction of relocation and territorial disputes within native peoples. Coronado's 1540 brutal search for the Seven Cities of Cibola caused Pueblo and Hopi groups to make alliances in order to protect their holdings in the upper Rio Grande valley. In 1598 the Onate and a group of Spanish settlers entered the central Rio Grande valley. Their presence forced Pueblo groups to reestablish themselves in a new configuration of alliance and mutual support.

Some native groups were able to maintain control of their territory and command a more powerful position with colonial and, later, American federal interests. The first treaties between native groups and the Euro-Americans were based on the strengths of two powers entering into treaties as equals. Native peoples agreed to allow Euro-Americans to inhabit certain spaces for mutual protection. In some cases, native treaty-makers did not perceive that what they were agreeing to was conceptualized in a very different way by the Euro-Americans. These natives could not conceive that what the Euro-Americans were doing was acquiring full rights to the land base because the natives did not believe that land was owned or tenured to any one specific group.

Once established, however, Euro-Americans continued to acquire and use land beyond treaty boundaries. This form of disrespect for the treaties caused continue disruption of native use

of resources, attempts to live with the new population, and peaceful relations with other native groups. Native peoples also faced disequilibrium as Euro-American settlement spread westward across the continent. Debilitating diseases, alcohol, and physical attacks rapidly reduced native populations.

Native groups in the west, especially the Nez Perce, quickly adapted to the use of horses. The introduction of horses added speed and the ability to cover large distances to these native cultures. By the time the American and Canadian governments made contact with these culture groups, their strength in hunting and raiding proved them to be powerful forces that stood in the way of the federal governments.

By 1830, native groups across the continent were significantly reduced and very strongly affected by the presence of the American and Canadian governments. Population numbers were greatly reduced and in some cases entire culture groups were wiped out. Both governments carried out major campaigns to exterminate native peoples. Those remaining were required to sign treaties that established reservations for native groups. Groups of differing traditional backgrounds were often placed on the same reservations. For example, the Cherokee of the southeast mound-building culture were forced to walk nearly a thousand miles in the winter of 1839 to a reservation established for them in the southern Great Plains. The walk, known as the *Trail of Tears*, resulted in the loss of hundreds of Cherokee lives. Those who survived the walk found themselves in a completely new physical environment for which they were not prepared. They were settled with other native groups with whom they shared little in common. Such conditions continued to undermine natives' ability to maintain cultural identity until the late 1870s. Populations were required to stay on reservations that were inadequate and unable to supply the needs of traditional peoples. Population numbers continued to decline.

Both American and Canadian governments, with the assistance of well-meaning missionary groups, assumed that native peoples would fit into a Euro-American North America if they

became farmers. Both governments instituted assistance programs and land tenure policies intended to assist natives into assimilating in the agricultural economies of the United States and Canada. These programs ultimately failed although some natives became farmers. The overall process continued to reduce native populations and open native lands for white settlement.

In a reversal of policy, the federal governments instituted new programs in the mid-twentieth century with the goals of creating tribal governance and business programs for native revenues and protection of native cultures. These new programs assisted native groups in developing tribal resources on tribal lands. Some tribes such as the Mescalero Apache, the Confederated Tribes of the Warm Springs, and the Red Lake Band of the Chippewa developed timber and cattle enterprises. The revenues from these enterprises helped to support native educational, health, and social services needs. However, the revenues were never large enough to fully empower the tribes. Tribes continued to be dependent upon federal programs for basic needs. These programs were unequally and generally poorly funded and administered. The distribution and quality of services on reservations was far from adequate.

The federal governments choose to eliminate many of the native programs at the end of World War II. The American government terminated reservations and treaties in many areas of the United States. All tribes, even those who had created profitable enterprises, were disrupted by these termination policies. At the same time, natives were encouraged to move to urban areas and learn skills that would allow them to find jobs and reside away from rural reservations. As a result of these policies, today the highest population concentrations of native populations in both Canada and the United States are in urban areas.

Contemporary Geographies of Native Peoples

The last decades of the twentieth century saw another policy reversal by both federal

governments. Working with native leaders, both governments are now committed to a process of native self-determination. Native groups have recovered some of their powers as established in treaties and have also been able to secure religious, burial, and cultural freedoms through national laws. As natural resources have become scarce in North America, it is increasingly evident that negotiations with native groups are essential in protecting habitats and threatened species, watersheds, major landforms, and critical wetlands. Native peoples continue to develop resources such as fishing and timber to meet their own needs. Native groups have quickly adopted technologies such as geographic information systems to maintain and plan resource management on native lands. Propagation and protection of flora for medicinal purposes have become major foci of native peoples. The Bella Coola and bands of Puget Sound natives have, for example, reclaimed land and protected specific species that play a significant role in cultural identity and health.

Native groups in the United States have exercised the right to develop casinos on native lands. The popularity of gambling and a desire to meet that need with additional casinos has required extensive mapping to identify the exact location of native lands. Revenue from gambling has been invested in resource development and cultural identity programs that support native populations. In some cases, casino revenue has made it possible for native groups to extend financial assistance to other cultural groups including the dominant white culture in local areas. Mutual resource management goals are also being identified and shared by more than one racial and ethnic group.

First Peoples in Canada have recovered major portions of the Northern Territories as part of the new native province of Nunavut (Atlas of Canada). Native peoples who are implementing traditional ideals and ways of knowing administer this province. Place names, the location of sacred places, resource gathering techniques, and social affairs are practices in Inuit traditions. Native groups throughout North America are experiencing a resurgence of cultural identity as the

landscape of North America reflects growing acceptance of a plurality of cultures.

Today, the largest growing populations in North America are native. More than half of all native peoples is below the age of 15. This growth rate requires planning and development of tribal resources. This expanding native population is able to access both the traditional knowledge of their cultural past and the freedom to express their native identity. The new emphasis on native knowledge is ultimately changing the power relationship between federal and tribal governments, the rights of native peoples, and the cultural and geographical record of the native populations of North America. With full recognition of native power and self-identification, this short essay is offered as only an introduction to the multidimensional and cultural diversity found among native North Americans.

Geomancy in China

Hong-Key Yoon

The University of Auckland, Auckland,
New Zealand

The Chinese word for geomancy is *feng shui*, which means “wind and water,” or *ti-li*, which means “the principles (patterns) of the land.” The term *ti-li* is also the Chinese word for geography, which suggests an intimate relationship between Chinese geomancy and geography.

In Chinese geomancy, a place having certain landforms and orientations is believed to be more auspicious than others. An auspicious place is where vital energy (*sheng-ji*) is accumulated and available to humans who occupy the site. The function of vital energy is to give birth to and support all living things, and it is stored in certain places meeting geomantic requirements, blessing the people who use the site in harmony with the surrounding landscape.

The flow of vital energy underground (often through mountain ranges) is analogous to that of blood through the veins of the human body. Therefore, a geomancer’s job is to find a spot where vital energy is accumulated, in a similar way that an acupuncturist finds a critical spot of the body where a needle can be planted.

An auspicious site (geomancy cave) is sometimes compared with a melon on a vine. The nutrients from the soil are taken through the roots and transported through the vines to be stored in the melon before being consumed by humans. In a comparable manner, the vital energy flows underground through the veins and is deposited in the geomancy cave to be available for humans who use the place appropriately by building, for example, a house or a grave.

The most important geomantic condition of an auspicious site is that it be sheltered by a surrounding range of hills on three sides, with one side open. The range on the left (normally East) side is called “azure dragon”; the right (normally West) range, “white tiger”; and the hill behind an auspicious site is called the main

mountain or “black warrior.” A horseshoe-shaped basin is an auspicious site. The most desired orientation of the site should face south. The land also needs to have access to a watercourse; the most desirable ones flow slowly with many bends.

In geomancy, the people who occupy auspicious sites are believed to benefit from the land by enjoying longevity, accumulating wealth, or achieving fame in the world. Traditionally, geomancers were normally consulted when cities, temples, graves, and other human settlements were built. Professional geomancers are supposed to know how to choose an auspicious site by applying geomantic principles and can be seen as the traditional Chinese version of modern geomorphologists, location or landscape analysts, and architectural planning consultants.

It is virtually impossible to understand the East Asian cultural landscape without having knowledge of geomancy. For instance, important cities like Beijing and Nanjing in China, Seoul and Kaesong in Korea, and Kyoto and Nara in Japan all were chosen and planned geomantically. Thus, Chinese geomancy is defined as “a unique and comprehensive system of conceptualising the physical environment, which regulates human ecology by influencing man to select auspicious environments and to build harmonious structures (i.e., graves, houses, and sites) on them” (Yoon, 1976).

In the evaluation of the quality of the landscape (the environment, place) in geomancy, the following three images are important. First, the landscape is perceived as a magical being which can influence people mysteriously, either auspiciously or inauspiciously. An auspicious site can bless people with a happy life, whereas an inauspicious site can cause people to suffer misfortunes, including disease, bankruptcy, death, and infertility.

Secondly, the landscape is personified and regarded as a system of either a living organism or an inanimate object. Either an element of a local landscape, such as a hill or stream, or the entire landscape itself may be treated as a functioning system of an object such as a cow, a boat, or a flower. Personification of a landscape

Geomancy in China,

Fig. 1 A geomantic compass currently in use by professional geomancers

G

as a beautiful, balanced, and peaceful object normally indicates an auspicious site, whereas personification as an ugly, dangerous, and unbalanced object suggests an inauspicious site. Depending on how a geomancer perceives a local landscape, it may be compared to (personified as) any object in the world.

Thirdly, the landscape is seen as a vulnerable being, which can easily be hurt or remedied by human interference, because the vital energy that flows beneath the surface is extremely vulnerable. Vital energy is only one particular phase of the *yin-yang* energy according to a geomantic classic called *Zang-shu*. When *yin-yang* energy belches out, it becomes the wind. When the wind ascends, it becomes a cloud. When it descends, it becomes rain. When it flows under the ground, it becomes vital energy, but when it emerges out of the ground, it is no longer vital energy (*Guo Bu*). That is why the vital energy of an auspicious site should be utilized without disturbing it, by building a house or a grave in harmony with the surrounding landscape.

In the history of China, geomancy was often more popular for choosing an auspicious site for

a grave rather than for a house, although the same geomantic principles were applied for both cases. All the important principles concerning an auspicious place are in fact about ideal conditions relating to a living person's dwelling site. The analysis of geomantic principles concerning auspicious locations suggests that Chinese geomancy began as an art of selecting a comfortable place to live and then came to be applied to selecting grave sites as well (Fig. 1).

By the sixth and seventh centuries, geomantic principles as we know them today were probably well established in China. Ever since then, geomancy in China has been a powerful part of the art of environmental planning, landscape design, and determining various types of settlement location.

This art was probably diffused to Korea with an early wave of Chinese cultural diffusion. Koreans in turn introduced this art to Japan. Judging from ancient capital sites in Korea and Japan, this art was introduced and practiced in those countries by the seventh century. Geomancy is still practiced in China, Taiwan, Hong Kong, Singapore, Korea, and Japan. In fact,

in Hong Kong, Singapore, and Korea, a number of geomantic institutes were established, and professional geomancers practice their art in planning building structures and in the selection of residential and gravesites.

Geomancy has been adapted to the modern urban environment, and even many Chinese living in cities like America apply geomantic principles in selecting their house sites and designing house structures. In city situations, the main points of geomantic considerations are in place of the landform conditions, street patterns, roof lines of neighbors, the shape and situation of a house section, and the floor plan of a house. In some cases, the furniture arrangement inside a house is decided by applying Chinese geomancy to present day city dwellings.

There have been numerous geomantic textbooks and manuals throughout the history of China, and even now, there are more than a dozen printed editions of geomantic books available for purchase in the Chinese language alone.

Geomancy in the Islamic World

Emilie Savage-Smith

The term geomancy comes from the Latin *geomantia*, first used in Spain in the twelfth century as a translation of the Arabic ‘ilm al-raml (the science of sand), the most common name for this type of divination. The practice is to be distinguished from a totally unrelated Chinese form of prognostication based on land forms, unfortunately also called geomancy in English. The origin of this distinctly Islamic art is a matter of speculation, but it appears to have been a well established practice in North Africa, Egypt, and Syria by the twelfth century.

The divination is accomplished by forming and then interpreting a design, called a geomantic tableau, consisting of 16 positions, each of which is occupied by a geomantic figure. The figures occupying the first four positions are determined by marking 16 horizontal lines of dots on a piece of paper or a dust board. Each row of dots is examined to determine if it is odd or even and is then represented by one or two dots accordingly. Each figure is then formed of a vertical column of

four marks, each of which is either one or two dots. The first four figures, generated by lines made while the questioner concentrates upon the question, are placed side by side in a row from right to left. From these four figures the remaining 12 positions in the tableau are produced according to set procedures. Various interpretative methods are advocated by geomancers for reading the tableau, often depending upon the nature of the question asked. The course and seriousness of an illness, the outcome of pregnancy, the location of lost or buried objects, and the fate of a distant relative are among the most popular questions addressed to a geomancer.

The acknowledged master of geomancy was Abū ‘Abdallāh Muḥammad ibn ‘Uthmān al-Zanātī, who lived before AD 1230. Virtually nothing is known of his life, though his name suggests that he was from the North African Berber tribe of Zanāta that was known for practicing other forms of fortune telling, particularly scapulomancy (divination by inspection of shoulder blades). One of the great codifiers of geomancy was ‘Abdallāh ibn Maḥfūf who lived, probably in Syria or Egypt, before AD 1265 and whose treatise is preserved today in several Arabic manuscript copies. Brief discussions of geomancy are included in a Persian encyclopedia composed at the end of the twelfth century by the celebrated theologian Fakr al-Dīn ► [al-Rāzī](#) and in short Persian tracts by the mathematician, philosopher, and founder of the observatory at Maragha in northwest Iran, ► [Naṣīr al-Dīn al-Ṭūsī](#) (d. AD 1275).

The majority of existing treatises on the subject are from the fourteenth century and later, with numerous ones still being written in the nineteenth and twentieth centuries. In view of the relatively few written sources on the topic before the fourteenth century, an intricate metal geomantic tablet, now in the collections of the British Museum, is of considerable importance. It was made in AD 1241–1242 (H. 639) by the metalworker Muḥammad ibn Khutlukh al-Mawṣilī, who also made an incense burner in Damascus about AD 1230–1240. This unique device is of a brass alloy inlaid with gold and silver, with a front plate carrying 20 dials and four

sliding arcs and a back plate engraved with inscriptions, both plates held in a rectangular frame which has a triangular suspensory device on top similar to that commonly found on astrolabes. No writings before or after its construction mention such a mechanical contrivance for establishing a geomantic reading, and there is no other known geomantic device from any culture remotely similar to it. It is evident that the designer of this elaborate device was well-versed in the geomantic literature of his day.

In Iran the term *raml* is applied to two types of divination. One type, frequently described by travelers, employed the throwing of brass dice that were strung together in groups of four. Although these dice are commonly referred to as geomantic dice, they are not marked so as to produce a geomantic figure, and thus the divination using such dice is a form of lot casting or sortilege different from true geomancy. *Raml* is also used in Iran for the traditional form of geomancy, and in modern Persian writings the art often attains an astounding degree of complexity, with successive tableaux generated from previous ones. A large number of lithographed Persian texts were published in India in the nineteenth century.

From the twelfth century until the seventeenth century, geomancy, in a slightly altered form, was very popular in Europe, where only astrology seems to have outranked it in popularity. The Spanish translator Hugh of Santalla working at Tarazona in Aragon appears to have been the first to prepare a Latin paraphrase of an Arabic treatise on the subject, with his slightly younger contemporary working in Toledo, Gerard of Cremona (d. AD 1187), translating another Arabic tract. After the seventeenth century, interest in geomancy faded abruptly in the West, and today it remains relatively unknown there.

There are many non-Western areas where geomancy and derivative methods of divination are still practiced. Geomancy in sub-Saharan Africa and Madagascar, which employs simplified but clearly derivative versions of classical Islamic geomancy, has been the subject of several anthropological studies. The mathematical structure of the practice has also received some scholarly

attention. In nearly all Islamic lands geomancy and related methods of divination are still practiced, in forms varying from the simple casting of a favorable or unfavorable geomantic figure to the complex interpretation of tableaux employing a large number of procedures.

abstract space and the relationships induced by that partitioning. Historically, as a human activity, it is said by the Roman historian Herodotus (d. 425 BCE) to have begun in Egypt where the annual inundation of the Nile River obliterated field boundaries. In order to preserve the royal system of land distribution and taxation, official priest-surveyors measured the land and reestablished boundary markers. Their land-measuring techniques were imported to Greece and given the collective name “geometry” (*geo*, “earth”; *metrein*, “to measure”). Thus the practices of land measurement became the science of geometry. However, all peoples and societies possess and use some geometrical knowledge. For example, decorative pottery motifs and textile or basket weaving patterns demonstrate a geometric knowledge and facility on the part of their creators. Certainly the blanket patterns of the Ibans of Borneo and the rafter carvings of New Zealand's Maori people reflect an appreciation of symmetry; a complexity of line relationships is evident in the *sona* tracings of the Tshokwe culture in southern Africa, and a mastery of geometrical figures is illustrated in the sand drawings of North America's Navajos. All these non-Western cultures possess “a geometry” but to survey these traditional geometries would present a monumental task and be beyond the scope of this present survey. Therefore the discussion below will view geometry in a narrower sense, i.e., as an exact science and as a subject of acknowledged societal concern either documented by existing historical records or the evidence of archeological excavations.

Egypt and Babylonia

Egyptian geometry was practical in its conception and tied to measurement and the bureaucratic needs of the state. A small collection of surviving papyrus problems provided a limited glimpse into the workings of Egyptian geometry. The ancient Egyptians possessed correct computation formulas for determining the areas and volumes for a variety of plane and solid figures.

Geometry

Frank J. Swetz

Geometry is the branch of mathematics that deals with the partitioning of a physical or

Apparently they deduced such formulas by techniques of “dissection and rearrangement.” Correct formulas for the areas of rectangles, triangles, and isosceles trapezia were employed. Problem 50 of the Ahmes Papyrus (1650 BCE) gives the area of a circle with known diameter d as $A = (8/9d)^2$ from which it is found that the Egyptians of this time used a value $\pi \approx 3.1605$. Problem 48 of the same sequence provides an illustration that has been interpreted as a polygonal approximation for the area of a circle and from which the formula was derived. In total, the Ahmes Papyrus contains 19 problems of a geometrical nature. The Moscow Papyrus (1850 BCE), in its 14th problem, offers a correct computational procedure for determining the volume of a truncated square pyramid of given height h and with bases whose sides measure a and b in length; $V = h/3(a^2 + ab + b^2)$. Problem 10 of the Moscow Papyrus requires the surface area of a “basket” with known diameter and has resulted in a yet unresolved controversy as to whether the Egyptians were considering the basket as a hemisphere or as a semicylinder. If the former interpretation is accepted this would indicate that the Egyptians possessed rather sophisticated geometrical insights at a very early date. Egyptian geometry remained utilitarian in nature and was never advanced to the status of an abstract science.

In a similar manner, Babylonian geometry was also of a computational nature and devoted to solving practical problems. In our context, the term “Babylonian” designates the civilization that occupied the Tigris-Euphrates region in the period 3500–539 BCE and includes the Sumerian, Akkadian, Chaldean, and Assyrian peoples. Knowledge of Babylonian geometry has been obtained from a limited examination of cuneiform texts and mathematical tables. This examination reveals that their authors possessed computation procedures for obtaining the areas of rectangles, right-angled triangles, isosceles triangles, and trapezia with one side perpendicular to the parallel sides. They knew several numerical properties of a circle and approximated the area of a given circle radius r by $A = 3r^2$. A clay tablet from the Old Babylonian Period (1900–1650

BCE) supplies a more accurate value of π as 3.125. The Babylonians could determine the length of a chord l , given the diameter of a circle d and the length of the sagitta in question a : $l = \sqrt{d^2 - (d - 2a)^2}$. Tablet no. 322 in the Plimpton Collection at Columbia University, whose origin is traced to 1800–1650 BCE, provides a list of Pythagorean triples indicating that the Babylonians of this period were familiar with the “Pythagorean Theorem.” A clay tablet excavated at Tell Harmal in Iraq and dated to about 2000 BCE indicates that its users knew some properties of similar triangles and could employ these properties in solving numerical problems involving triangles. Babylonian scribes also could compute the volumes for simple solids and possessed an approximate formula for the volume of a truncated square pyramid of height h and bases of length a and b , i.e., $V = h/2(a^2 + b^2)$. Although several excavated clay tablets bear geometric diagrams, these diagrams serve as illustrations for relevant concrete problem situations and are not theoretical constructions. Apparently for the Babylonians, geometry remained an adjunct to numerical problem solving and did not evolve into a separate discipline.

Ancient India

Geometric activity on the Indian subcontinent can be traced back to the Indus Valley Civilization (ca. 3000 BCE). Excavations at this civilization’s urban centers of Harappa, Lothal, and Mohenjo-Daro reveal the existence of a baked-brick technology allowing for the erection of numerous structures: houses, baths, and market places. This construction entailed large-scale city planning and the use of geometry. Archeological evidence indicates that the Indus peoples were familiar with the basic properties of rectangles, triangles, and circles, and could employ right-triangle principles for planning and structural purposes.

With the arrival and dominance of the Aryan culture in the region (1500–800 BCE), there

developed a sacred Vedic literature of rituals and customs. Part of this literature concerned the construction of sacrificial fire altars of specific shapes and dimensions. Cord stretching techniques were described to obtain the required results. This collection of construction procedures and techniques became known as the *Śulbasūtras* (800 BCE) or “the rules of the cord.” Using cords and pegs, squares, circles, rectangles, and trapezia of specified dimensions and areas could be laid out and constructed by the Vedic priests. Although outwardly religious texts, the *Śulbasūtras* presented a codified system of geometry. Besides obvious geometric constructions, the texts supplied a technical vocabulary for geometrical principles and concepts including a theory of similar triangles. Techniques for transforming shapes while preserving areas considered the quadrature of rectangles and circles, and procedures were also given for doubling the area of a circle and transforming a square into a circle. The principle of constructing a square on the diagonal of a rectangle (“Pythagorean Theorem”) was also known to the writers of *Śulbasūtras*. No formal “proofs” were given but some results were justified by arguments.

The subsequent influence of the *Śulbasūtras* on the latter development of Indian geometry is controversial: early researchers such as G. R. Kaye could discern no influence, whereas more modern writers such as T. A. Sarasvati Amma believe that the *Śulbasūtras* established the foundation for all Indian geometry. Whatever the influence of these Veda texts on geometrical thinking, later developments in this field were spotty and isolated. Geometry became closely associated with astronomy and cosmography. It was dominated by numerical problem solving based primarily on the use of right-triangle principles and was mainly concerned with finding the length of circular chords. The post-Vedic period saw the rise of the Jaina school of philosophical and scientific thought. The Jainas, in their cosmological considerations, held two geometric figures – the circle and trapezium – in high regard. Much of their geometry focused on mensuration problems involving these figures.

In general, they considered geometry important denoting it as “the lotus of mathematics.” The Jainas employed the approximation $\pi = \sqrt{10}$.

The next Indian mathematical text of note to appear was the *Āryabhaṭīya* (ca. 499) of Āryabhaṭa I (476–550). While many of its problems concern the applications of geometry to astronomy, its author also considered the computation of area for triangles, trapezia, and circles, and the volumes of spheres and triangular pyramids. Āryabhaṭa’s formula for the area of a circle is correct; his approximation for π is 62,832/20,000 or 3.1416. However, his results for the volume of a sphere are $V = \pi^{3/2}r^3$. Subsequent mathematical authors would refine and extend Āryabhaṭa’s work. ► [Brahmagupta](#) (ca. AD 628) in his *Brahmasphuṭasiddhānta* (Correct Astronomical System of Brahma) provided sections on *Ksetra* (plane figures), *Khāta* (cubic figures), *Citi* (solids composed of piles of bricks), *Krakaca* (truncated solids), and *Chāyā* (plane figures resulting from shadows). Much of Brahmagupta’s results are limited to triangles and quadrilaterals inscribable in a circle. His most notable findings include:

- The correct determination of the area of a cyclic quadrilateral of sides a, b, c, d , with s as its semiperimeter, i.e., $A = \sqrt{(s-a)(s-b)(s-c)(s-d)}$.
- The length of the quadrilateral’s diagonals d_1 and d_2 :

$$d_1 = \sqrt{\frac{(ac+bd)(ad+bc)}{(ab+cd)}},$$

$$d_2 = \sqrt{\frac{(ac+bd)(ab+cd)}{(ad+bc)}}.$$

- The volume of a cone as one-third the product of its base area and its height.

► [Mahāvīra](#) (ca. 850), a Jaina mathematician, improved upon Brahmagupta’s theories in his *Gaṇitasārasaṃgraha* (Summary Compendium of Mathematical Astronomy), greatly extending

geometric terminology and classification systems. For example, he divided quadrilaterals into five different subcategories: equal sides, opposite sides equal, etc., and triangles into three categories: equilateral, isosceles, and scalene. ► **Bhāskara II** (b. 1114), author of one of the most illustrious of Indian mathematical classics, *Līlāvātī* (The Beautiful), obtained accurate formulas for the volume and surface area of a sphere and obtained close approximations for the length of a circular arc in terms of its known chord. Mādhava of Sangamagrāmma (ca. 1340–1425), a Kerala astronomer, is noted for his work on the circle as well as spherical geometry.

Euclid's *Elements* were known and studied in India in the fourteenth century, but the first complete Sanskrit translation of this work appeared in 1718. The translation was performed by Jagannātha Samrāt at the request of his patron king astronomer Jayasimka of Jaipur.

The Islamic World

The founding of Islam in AD 622 was marked by the flight of Muḥammad from Mecca to Medina. Initially experiencing a period of rapid expansion, it was not until the founding of the Abbasid Caliphate, with the establishment of Baghdad as an intellectual and political center (AD 726) that Islamic civilization could begin to express its own intellectual and scientific traditions. The early Abbasid caliphs were patrons of the collection and translation of foreign scientific texts into Arabic, thus establishing a basis for Islamic science. Although Muslim scholars became the heirs of existing western (and eastern) scientific theories and traditions, they did not remain mere translators and passive communicators of this knowledge. In many fields they became true innovators and amplifiers of their mathematical and scientific inheritance. Geometry was one such field that was enriched by Islamic contributions.

The Greek sources that most influence Islamic geometric thinking were Euclid's *Elements*, Archimedes' *On the Sphere and Cylinder*, and

Apollonius of Perga's ► **Conics**, all of which found their way into Arabic during the eighth to the ninth centuries. Muslim geometers pursued the theoretical problems poised in these texts and used their principles in a wide variety of new applications, particularly the study of optics and the design of mathematical instruments. The earliest documented Islamic geometry appears as a separate section of al-Khwārizmī's *Kitāb al-mukhtaṣar fī ḥisāb al-jabr wa 'l-muqābala* (Compendious Book on Calculation by Completion and Balancing), where rules for mensuration and geometric computations involving areas and volumes are stated. The value of π is given as 31/7. Within 50 years of al-Khwārizmī's work, his successors were involved with far more complex geometric theories.

Thābit ibn Qurra (830–890) discussed the geometric verification of algebraic results in his *Qawl fī taṣḥīḥ masā'il al-jabr bi'l-barāhīn al-handasiyya* (On the Verification of Problems of Algebra by Geometrical Proofs). In a private correspondence with a colleague, he expressed dissatisfaction with the existing Socratic proof of the "Pythagorean Theorem" and went on to derive three new proofs, one of which provides a generalization of the theorem to all triangles. Thābit also wrote on the trisection of an angle problem. His grandson, Ibrāhīm ibn Sinan (d. 946), continued researching this problem and provided for "ruler and compass" constructions of the conic sections in his *Rasm al-quṭū' al-talātha* (Outline of Three Sections). In approximately AD 950, Abū'l Wafā' wrote a book on applied geometry for craftsman, *Kitāb fī mā yaḥtāj ilayh al-ṣāni' min al-a'māl al-handasiyya* (Book on Necessary Geometric Construction for the Artisan), in which he presented several original constructions for conic sections. Around the year 1000 Abū 'Abdullāh al-Ḥasan ibn al-Baghdādī published a comprehensive treatment of incommensurables improving on the theory given in the *Elements*.

One of the recurrent themes in Islamic geometry is the concept of parallel lines and the provability of Euclid's fifth postulate. Ibn al-Haytham (ca. 965–1039), known in the West

as Alhazen, attempted to reformulate Euclid's theory of parallel lines by assuming the constructibility of the lines. He presented his theory in a work entitled *Maqāla fī sharḥ muṣādarāt kitāb Uqlīdis* (Commentary on the Premises of Euclid's *Elements*). 'Umar ibn Ibrāhīm al-Khayyāmī, or 'Umar al-Khayyām (ca. 1048–1126), in investigating the concept of parallelism, developed a series of eight propositions eventually leading to the establishment of Euclid's fifth postulate. 'Umar al-Khayyām's work was based on the possible relationships of the angles of a quadrilateral. In turn, this work was expanded by ► [Naṣīr al-Dīn al-Ṭūsī](#) (1201–1274). He also explored parallelism with the aid of a quadrilateral, but allowed for the existence of acute and obtuse angles within the quadrilateral seeking to obtain a contradiction to his premises concurring the nature of parallel lines. He published his work on the fifth postulate in 1250; it was entitled *Al-risāla al-shāfiya 'an al-shakk fī al-khuṭūṭ al-mutawāziya* (Discussions which Remove Doubts about Parallel Lines).

Eventually the theories of Islamic scholars such as Ibn al-Haytham and al-Ṭūsī reached Europe; there they profoundly affected the nature of geometric thinking.

China and the Far East

Most geometrical considerations in early China were empirically based. However, during the Mohist school of activity (ca. 300 BCE) a deductive approach to understanding geometry was undertaken. Mohist philosophy and scientific theory were based on the use of logic. The Mohist Canon (*Mozi*) (ca. 330 BCE) develops a formalist approach to plane geometry building upon a concept of points and lines. Mohist theories did not become popular, and the development of a theoretical geometry progressed no further.

The earliest extant references specifically on Chinese mathematics are the ► [Zhoubi suanjing](#) (Arithmetical Classic of the Gnomon and the Circular Paths of Heaven) and *Jiuzhang suanshu* (Nine Chapters on the Mathematical Art, ca. 100 BCE). A discussion of right-triangle

relationships is given in *Zhoubi*, along with a dissection proof demonstrating that the sum of the squares of the sides adjacent to the right angle in a right triangle is equal to the square of the hypotenuse. Four chapters of the nine chapters of *Jiuzhang* are specifically devoted to geometrical computations involving areas, volumes, and work with right triangles. Correct procedures for finding a variety of areas and volumes are given; the area of a circle of radii r is noted as $A = \pi r^2$ with $\pi = 3$; but the volume of a sphere with diameter d is incorrectly found, $V = 9/16d^3$. An approximation for the area of a circular segment with chord C and sagitta S is given as $A = S/2(S + C)$. Similarity among right triangles is employed in several problem situations.

In the third century, the scholar Liu Hui wrote a commentary on the *Jiuzhang* in which he provided dissection proofs for many of its geometrical formulas. Liu also employed a circle dissection technique involving a 192-sided polygon to estimate π as 3.141024. He extended the right-triangle theory of the *Jiuzhang* to include more complex problem situations involving pairs of similar right triangles. Using a technique called *chong-cha*, Liu provided proofs for solution procedures and published his findings in an appendix to *Jiuzhang*. Eventually, this appendix became a separate geometrical classic called *Haidao suanjing* (Sea Island Mathematical Manual). ► [Zu Chongzhi](#) (429–500) refined Liu's approximation for π obtaining a value of 355/113 or 3.1415929. Further, using a geometric slicing technique, Zu found the volume of a sphere, radii r , correctly as $V = 4/3\pi r^3$.

In 656, the geometric theory contained in *Zhoubi suanjing*, *Jiuzhang suanshu*, and *Haidao suanjing* was sanctioned by the Tang dynasty as a formal curriculum for its scholar officials. This curriculum was also eventually adopted in Japan and Korea, establishing a limited geometrical outlook based on empirical problem solving. This outlook would remain unaltered until the sixteenth century when a translation of Euclid's *Elements* appeared in the Chinese language. This translation of the first six books of Euclid was made by the Jesuit missionary Matteo Ricci and the Chinese scholar Xu Guangxi.

Pre-Columbian America

Although no written records exist to document the geometric knowledge of the early Native American civilizations, archeological sites testify to their use and understanding of geometry. In particular, the city planning and construction techniques employed by the Olmec, Maya, Teotihuacan, Toltec, and Aztec peoples of South and Central America and the Anasazi of the North American Southwest indicate that these peoples utilized the properties of circles, squares, and rectangles and employed right-triangle theory.

Geometry and Architecture in the Americas

Mardith Schuetz-Miller
Red Bluff, CA, USA

Lost in the history of modern man's beginning is the origin of a universal worldview of a Cosmic Mountain centering the world, the *axis mundi*, topped by the Tree of Life with a bird at its apex and a body of water or four rivers emanating from its roots. The mountain (or surrogate pyramid) can also be viewed as the Earth Mother ("Mountain Mother" is an early epithet for her), the tree as the sky-pole inserted to separate heaven (generally male), and earth (generally female) as the initial act of creation. At the same time both pyramid and tree bridge the two worlds. The bird is the hen that laid the Cosmic Egg. Its halves became the earth and the sky and its contents the geographic and celestial features of the earth, as well as plants and animals. The bird, however, also symbolizes air, the breath of life, and the vehicle of souls. The water is the place of emergence for mankind into the present world following creations and destructions of previous worlds

This entry has been abstracted in part from Spider Grandmother and Other Avatars of the Moon Goddess in New World Sacred Architecture (Journal of the Southwest, special edition, Vol. 54, No 2, 2012).

by a creator attempting to perfect a race a people who live in harmony and pay proper homage to him, or her, and his, or her, dictates. Animal avatars of the gods varied across space, reflecting their natural habitat and totemic recognition over time.

Another image of this antique worldview is the serpent (snake, dragon, or crocodile). In some mythologies a snake or four snakes separate heaven and earth. The snake is therefore interchangeable with the tree as the bridge between earth and firmament. Additionally the Milky Way was viewed as a Cosmic Ocean in serpent form that encircled the earth and periodically destroyed the world in order to begin another.

The belief in a deity who destroyed previous worlds had several consequences. One was the idea of a tiered universe with previous worlds beneath and several above this one. In Buddhist cosmology, for example, both nine and thirteen levels are identified. Multiple worlds also led to concepts of cyclic time, envisioning future worlds to come, and ceremonial calendars demanding the symbolic re-creation of this one in the attempt to keep it in balance (often tied to dynastic changes) to stave off the next destruction. Thus, the construction or reconstruction of any kind of building deemed sacred – be it temple, king's palace, or priest's home – re-created (and still does in some cultures) the world and required a human sacrifice representing the creator, who by one means or another died in order to bring forth life.

The body of water divided into four rivers oriented to the cardinal points partitioned the world into quadrants, thus producing the quincunx with the mountain center as the fifth point. It is what I term the "Cosmic Cross." Its origin as a symbol of godhead at the center and a quadripartite universe is at least as old as 5600–4600 BCE in Anatolia and, enclosed in a circle, became the Pharaonic Egyptian hieroglyph for a town. In China each arm of the cross was represented by a distinct animal equated with the direction or by directional snakes or dragons.

An early representation of the creation story is a pictograph produced by ancestral Bushmen–Hottentots. It depicts a male creator

afloat on the abyssal sea, a bent knee (which becomes the mountain) with a bird perched on it, his phallus ejecting semen to begin life. A similar Egyptian example shows the male Earth God, Geb, in a nearly identical position with an erect penis reaching toward his sister-wife Nut, Goddess of the Air, who arches above him. At his head is the mountain hieroglyph and at his feet the hieroglyph for west, the entrance to the underworld, with the goose that laid the Cosmic Egg. A beautiful example of this worldview is a cult pillar from Knossos, Crete (dated from 2500 to 1400 BCE). The base takes the form of the temple/mountain from which grows the Tree of Life, topped with the double-axe symbol of the Great Goddess and the bird. A parallel, perhaps older, myth of creation has a Spider Mother (avatar of the Moon Goddess) who wove the world into being, defined its boundary, produced progenitors of the human race from her egg sacs, and served as general guide and culture hero to her progeny. Like other creator-gods, her gender changes from culture to culture and her negative side is the ubiquitous trickster – Ananse to the Ashanti of West Africa and Inktemi to the Sioux of North America, for examples. The Spider Mother can be understood as a totemic variation on the Cosmic Egg.

These worldviews are so ancient and widespread in their distribution that I presented a case for a common Paleolithic out-of-Africa origin for them in *Retrieving Tribal Memory* (Schuetz-Miller, 2011a, b, 2012a). This entry examines the continuity of worldview concepts and innovations in how they were manifested in some of the New World's more sophisticated architecture.

Ceremonial Centers of Peru

At about the same time (late fourth and third millennia BCE), Sumerians were erecting ziggurats, Egyptians building pyramids, and the Chinese laying out large sacred compounds. Indians of coastal, mid, and highland Peru began building sizeable ceremonial centers with resident

populations and monumental architecture in what is known as the Preceramic period (prior to ca. 2000 BCE). General characteristics of the temple complexes were large terraced platforms topped with a single or multiple buildings. Access to the summit or linking multiple mounds were projecting or inset stairs and/or ramps. Adobe or stone temples on top were plastered, painted, and sometimes decorated with incised or modeled religious motifs. Floors were of compacted clay and in the highlands were frequently split-level. Some platforms had gallery tombs entered from above for mass burials of men, women, and children. Sunken courts with opposing wedge-shaped inset stairs first appeared in the Supe valley and quickly spread to coastal and highland centers. Some coastal sites were enormous. Caral, for example, covered 65 ha, incorporated six large platforms, each associated with a complex for a class of elites. Within the center were two circular sunken plazas. Numerous outer zones included residential barrios for a lesser class. The coastal complexes, in contrast, dwarfed highland sites. (Data on South American sites are all from Burger, 1992, unless noted otherwise. Bracketed comments are by the author, 2012a, pp. 177–179, 192–204, 227–238, 277–279).

Evidence of ceremonialism is deduced from earlier rooms filled with rubble to provide a foundation for a new structure, sometimes enclosing the entire building to begin a terraced platform. Pits with flues sunk into floors were made for burnt offerings. Dedicatory offerings were found sealed within a room; others were buried between or under floors. And, finally, there were elaborate burials of nobles and/or priests with rich grave goods and sacrificed attendants. Offerings of cotton cloth, gourds [symbol of the womb] filled with food, bird feathers and down [symbolic of people derived from bird ancestors], unbaked clay figurines, bundles of both burnt and unburnt cotton [Moon Goddess as weaver], short sticks carved with chevrons or other geometric designs, pecten shells [attribute of the Moon Goddess], cotton string crosses [*ojos de dios*, protective web of the Spider creatress], a wooden bowl with carved frogs [another early

avatar of the goddess], a ceramic bottle decorated with intertwined snakes [progenitors of the human race in many mythologies], deer antlers [totemic ancestor of people], and a staircase painted with a white serpent [snake as bridge between heaven and earth], and the crossed hands of the Kotosh Religious Tradition point to a peaceful, benign worldview.

Within the ensuing Initial Period innovations in building style appeared: U-shaped temples in the central coast. Adobe cones were set into walls and pilastered rooms became characteristic of north central and northern coastal buildings. New artistic motifs were materialized: fanged monsters, a predominance of arachnid elements [jaguar or puma and spider as avatars of the Moon Goddess], and the earliest evidence of the shamanic use of the psychedelic San Pedro cactus. A painted door to the central room of a temple atop a terraced platform at Cerro Sechín featured a mural of large black felines. The base platform of a later building phase depicted a pair of large fish. The motif suggests the primordial world of a creative couple, such as Chinese Fuxi and Gaomei, frequently depicted as fish, and is consistent with New World mythologies describing a previous world inhabited by fish.

In the highlands great strides were made in construction and engineering that required careful advance planning. One was the ability to cut, move, and finely polish megalithic stone. At Sechín Alto, for example, blocks measuring 1.5 m to the side and weighing over two tons were used to face the terraced pyramid. (The site's central pyramid, by the way, achieved a height of 44 m, the equivalent of a nine story building.) At some sites walls were built with large blocks between stone uprights. The earliest use of volcanic tufa appeared. The apex of Peruvian Initial Period construction was achieved at Chavín de Huántar. Stone mortise and tenon joinery embedded sculpted heads into walls and secured the nearly 15-foot jaguar monster with snake hair colossus known as the “Lanzón” into the floor and ceiling of a small cruciform chamber – the Holy of Holies. Complex systems of stone-lined ventilation shafts and drainage canals, even one extending under a circular

court, attest to skill in hydraulic engineering. Over several 100 years builders enlarged older structures and added new ones, using white granite and black limestone, suggesting a dualistic belief as it was in Southeast Asia. Chavín became a great cult center, attracting pilgrims from great distances, thus spreading the Chavín artistic style. The great highland city-states, under their theocratic societies, transitioned into the Early Horizon under peaceful conditions, setting the stage for the great ceremonial centers around Lake Titicaca and the Inca Empire in the Current Epoch.

About 900 BCE, as highland cities were flourishing during the terminal Initial Period, the majestic coastal centers began disintegrating among evidence of intersocietal warfare. They began to construct citadels on defensible hill sites of the north central coast, multiple-walled enclosures with heavy buttresses, bastions, baffled entrances, and moats for starters. With rare exceptions, new ceremonial centers were not established and some old ones were abandoned during the succeeding Early Horizon. Incised and painted clay friezes depicting dead people with blood flowing from their skulls, warriors, trophy heads, severed limbs, gouged eyes, etc. point to the ferocity of the times.

Building Technology, Archaeoastronomy, and Pre-Euclidean Geometry

From site data and written descriptions from the later Inca period, we glean insight into construction techniques and instruments. Master builders worked from drawings and models. Towns and buildings were laid out with cords (the cord could also be used as a compass). A socketed ceramic device served as a primitive transit used with rods pierced with eyeholes for measuring 90° angles. The needlelike rods resemble those held by so-called Staff Gods, a reminder that geometry and measurement re-created the skyscape and were sacred activities, just as the cord, symbol of the umbilicus connecting heaven and earth was itself sacred. Stone was quarried by drilling slots

into the rock, inserting wooden wedges, and pouring water over them to cause them to swell and split the rock. Ashlars were cut using grooved channels. Stones were dragged with braided sinews or llama skin and set into place with the use of ramps. By Inca times copper axes largely replaced stone ones. Masons mixed straw into adobe to prevent cracking, applied cactus juice to both exterior and interior walls to help the mortar adhere, and added wool or finely ground straw to mortars to produce a glossy finish (Betanzos, 1996, p. 70; Burger, 1992, p. 115; Cobo, 1990, p. 240; Milla Villena, 1992, pp. 120, 152; Schuetz-Miller, 2012b, pp. 334–339).

Through millennia of observation of the night sky, our ancestors accrued a thorough knowledge of the annual progression of stars and planets. It was the single constant in an unpredictable and often hostile world. The appearance of a star or constellation recalled a myth, signaled a time to start or abstain from hunting or fishing, a time for planting and harvesting, as well as providing a ceremonial calendar. The firmament was the realm of the gods and ancestors. Indeed, brilliant stars or planets were deities themselves and if man-made sacred spaces mirrored the heavenly abodes of holy people, they would look favorably upon them. Therefore, it is not surprising to find ceremonial structures oriented with certain asterisms. Numerous sites stretching along most of the vertical length of the west coast of South America, dating back to the Preceramic period, are oriented with the Southern Cross (seen as a condor chasing the Celestial Llama, identified in Centaur with Alpha and Beta as the eyes, or a llama doe suckling her fawn). Summer solstice and equinoctial alignments are evident at other coastal sites. Some Andean centers face the rising of the Pleiades (identified by Barsana as Star Woman who governs the seasons and agriculture). Others appear to be oriented to the zenith and nadir sun directions. The doorway of one temple has sight lines on the rising positions of the sun and Pleiades. Astronomers in the coastal valleys observed the heliacal rising and setting of Orion's Belt (the Desanas recognized Orion as the trickster creator/culture hero with

a prodigious sexual appetite who violated his mother-in-law), the Southern Cross, and several dark cloud constellations. Almost two millennia prior to the erection of the Sun Pillars of Incan Cuzco, a solar observatory was built at Chankillo 400 km north of Lima. Thirteen towers along a north–south axis mark the progress of the sun between winter and summer solstice from observation points within adjacent buildings to the west and east during a time frame of about 300 BCE. Incan Cuzco had an elaborate pattern of 41 radiating sight lines, some astronomical, incorporating both natural and man-made shrines called *huacas*. Machu Picchu and Pisac had multiple observatories, including the former’s Intihuatana for solar observation carved from the living rock.

A system of pre-Euclidean geometry evolved from tracking the courses of the sun and moon. Daily sightings of the rising and setting points of the sun throughout the year produced a circle. The circle was divided by observations of the summer and winter solstices and again by the twice annual occurrence of the equinox. The basic forms of geometry were now established: the circle and the halving of it with the solstices or the equinoxes. The circle could be divided into quadrants by intersecting the half at right angles or by the intersection of the two solstices which approximates a 90° angle. By connecting the points, a square is produced. By connecting diagonally opposite points of the square, two triangles are formed. Connecting the points of a cross dividing the square into quadrants and the corners of the square with the two farthest diagonal points result in an eight-pointed star, a symbol of divinity. It was a geometric system used for designing a single structure or laying out great ceremonial complexes in Mesopotamia, perhaps as early as 4500–4000 BCE (Brunés, 1967; Schuetz-Miller, 2006, pp. 331–332; Schuetz-Miller, 2011a, pp. 212–216).

Pre-Euclidean geometry was used in the Americas as well. Noted previously were enigmatic circular sunken courts with wedge-shaped steps. They are often referred to as “kiva courts” because of their resemblance to Pueblo keyhole kivas. They were likely filled with water to serve

as celestial mirrors or observatories; clay effigy pots made later portray figures holding them or peering into them. According to Milla Villena, the most important celestial event to Andinos was the zenith position of the Southern Cross; the ratio of its width to its length, the square root of 2, was a sacred proportion. My analyses of a kiva court (Figs. 1 and 2) compared to a Pueblo kiva (Figs. 3 and 4) confirm the use of root 2 extensions, as well as the eight-pointed star and doubling the square.

Figure 5 demonstrates that a lateral extension to a central temple was likewise dictated by the square root of 2 (Milla Villena, 1992, pp. 60, 62, 107–108, 121–123; Schuetz-Miller, 2012b, pp. 309–312).

Ceremonial Centers of Mesoamerica

Noted earlier was the inner sanctum constructed as a cruciform chamber with the Lanzón colossus (part jaguar, part snake – both aspects of the Moon Goddess and equated with water – small cruciform symbols enclosed in circles at the corners of the mouth) at Chavín de Huántar.

Recovered from excavations at Chavín was a small mortar carved as a jaguar with cruciform spots. These symbols lead us to Mesoamerica’s first great civilization, the Olmec culture. For years the heartland appeared to have been in the Mexican states of Vera Cruz and Tabasco, its influence (from ca. 1200 to 400 BCE) reaching as far north as Mexico City, as far south as Honduras, and across the Isthmus of Tehuantepec to the Pacific and giving rise to the Maya and Aztec civilizations. However, more recently discovered Olmec sites along the Pacific coast in the states of Guerrero, Chiapas, and Guatemala, with earlier dates going back to 2000 and 1400 BCE, contest the traditional birthplace.

La Venta, built between 1000 and 600 BCE, may have been unique in constructing a replica of a volcano rather than the usual pyramid substitute. A stele at its base represents the Tree of Life and Olmec kings identified themselves with the tree, harkening back to a time when gods were recognized in menhirs [standing stones] and had

Geometry and Architecture in the Americas, Fig. 1

Kiva court, Haldas, Peru. The *left* analysis shows that the staircases were derived from the eight-pointed star. The *right* shows the use of the doubling of the square root of 2 extensions (Based upon a drawing of the site in Milla Villena, *Génesis de la cultura andina*)

tree forms in the Old World. Within a sunken court before the “volcano,” green serpentine mosaic pavements with tasseled edges, representing aquatic vegetation and flowers, re-created the Primordial Sea – an immense effort which was then buried to indicate it was the underworld (Freidel, Schele, & Parker, 1993, pp. 132–137). Also buried at La Venta was an enigmatic tableau of carved serpentine and jade figurines and axes. Like Peruvian temple complexes, Olmec ceremonial sites typically had tall pyramids at north and south ends of a plaza with platforms, once topped with lesser temples, and tombs aligned symmetrically between them delineating the sacred space. Excavated sites show considerable rebuilding of structures under different kings. Since latex balls have been found, at least at one site, ball courts are likely to be found eventually (Stuart, 1993, pp. 88–115).

In Olmec art the equal-armed cross represents a deity, either female or male, and is often found associated with a feline. In the Yucatecan and

Cholan languages, the cross is known as the *kan* and *chan*, respectively, meaning “sky,” “snake,” and “four.” Some platforms and tombs at early Monte Alban were constructed in the form of the Cosmic Cross. The Zapotecs appear to have equated the arms with the lesser lightnings (clouds, rain, hail, wind), represented by lizards that were aspects of Cocijio (Lightning), the most powerful force in Zapotec belief. In the southeastern USA, the cross was a popular motif on artifacts produced by the Hopewell, Adena, and Mississippian cultures. Figure 6 depicts Spider Grandmother, an avatar of the Moon Goddess, delineating the world as in a Zuni version: “[Water Strider] stretched out his [sic] arms and legs and touched the horizon at the north, west, south, and east. He was in the middle of the world.” In addition to the gorget [piece of armor surrounding the throat] depicted, others feature the Cosmic Cross, symbolizing the life force, with other avatars of the goddess, such as directional felines, rattlesnakes, and pileated woodpeckers.

The feline (jaguar or puma) was surely the most prominent avatar of the creatress in Olmec culture. The ubiquitous representations of a fanged, snarling face with downturned mouth, the Witz Monster, and the same images with a cleft head are all the felines as Earth Mother. The latter possibly symbolized either the theme of the mother who had to be sacrificed for her body to become the earth and start the process of creation or the cave opening (both mouth and birth canal) of the Earth Mother as Cosmic Mountain at the center of the Cosmic Cross (Schuetz-Miller, 2012a, pp. 192–200, 211–220).

In this proposed direct link between Chavín, the Olmec of Mesoamerica, and the southeastern USA, important clues are Chavín's sunken court and the plethora of feline and arachnid imagery. While the courts probably served as celestial mirrors, as suggested by Milla Villena, I think

they also symbolized the Place of Emergence through which Spider Grandmother led the survivors of a previous world through a body of water into this, the Fourth World. Impressed into the floor of Chavín's court was a large fossilized gastropod identifying it as the Cosmic Sea (Milky Way, also viewed as a snake) encompassing the earth. Conservative tribes of the Americas retain the creation story in their constructions. Tucanoans envision the earth as an enormous hexagonal spider web outlined by six outstretched snakes. Their longhouse is built over a web wherein dwells the spider. Radial and wheel-shaped patterns of other Brazilian tribes likely reflect the same worldview. Altars in Huichol temples of western Mexico mark the watery underworld of the Mother of the Western Sea who sometimes appears as a spider. Underground kivas of the Pueblo people of the southwestern

Geometry and Architecture in the Americas, Fig. 5 Huaca de los Reyes, Peru. Cupisnique Initial period complex (Drawing based on original map by T. Pozarski in Burger, *Chavín and the Origins of Andean Civilization*)

USA also represent the entry into the Fourth World. The structure is the primordial underworld home when the gods (*kachinas*) are in residence. Their impersonators reenact the

original emergence when they climb out of the kiva for ceremonies (Schuetz-Miller, 2012b, pp. 302–303, 319, 359). Returning to Olmec culture, a sunken courtyard at Teopantecuanitlán

Geometry and Architecture in the Americas,
Fig. 6 Shell gorget, Southern Cult Temple, Mound II,
 Perry County, Missouri (Redrawn from Griffin, *Archeology of Eastern United States*)

(“place of the temple of the jaguar gods”) has two of its four walls adorned with jaguar heads carved of travertine (Stuart, 1993, pp. 108–109, 114). It echoes Chavín’s sunken court in which paired jaguars carved into the walls converge toward the western staircase; the west is the home of the Moon Goddess (Schuetz-Miller, p. 319).

Carrying the concept into the Mayan period, we have the advantage of written records and archaeology, to further our understanding of sacred spaces. Mayan ball courts similarly represented the underworld (Xibalba) where Hun-Hunahpu, father of the hero twins (who became the Sun and Moon), was lured by the evil beings to play ball, was defeated and decapitated. An extraordinary example of the re-creation of this world is found at Copan, Honduras. In its final stage of rebuilding (dedication date January 7, A.D. 738), a mountain/temple was erected at the north end of the plaza, its entry fashioned as the maw of the Jaguar Monster. At the corners of the building, other carved jaguar heads, topped with maize stalks and celestial birds, were embedded. Framing the interior

side of the entrance was a deeply carved Cosmic Monster, an anaconda with a crocodilian head decorated with Venus symbols. The walls of a false ball court below the temple were adorned with carved conch shells; caymans [reptiles] on a platform overlooked it. Centered on the western staircase leading down to the court was a sculptured image, and hieroglyphics identify it as Chac-Xib-Chac (evening star – an aspect of Venus, the first-born of the twins). Flanking the stairs, there is a pair of dancing jaguars – the hero twins celebrating their victory over the Lords of Death. At the center of the court were three markers depicting the severed head of the First Father (Freidel et al., 1993, pp. 146–155); Schele & Freidel, 1990, pp. 322–323, 489 n.44

At Copan we find all the universal symbolism of man’s early cosmic view of the world. At its center are the mythic pyramid/mountain as the *axis mundi* and the temple in the form of the feline monster, the Earth Mother associated with rain, fertility, and childbirth. It has the same significance as the temple at Peruvian Cerro Sechín with its doors painted with felines. The corn stalks represent the Tree of Life atop the mountain and the birds that top them the vital Life Force (air, breath, spirit). The ball court, like Peruvian kiva courts, is the body of water at the roots of the tree and base of the mountain – the entrance to the underworld and the intersection of the four rivers and four quarters of the earth. There is the earth-enclosing ocean in the form of a serpent seen in the Milky Way. And finally there is the association of the feline with shamanism and its persistence to this day in the Olmec heartland and Amazonia (Schuetz-Miller, 2012a).

The Cosmic Cross or quincunx persisted as the model for pyramids throughout pre-Columbian kingdoms. It remains the perceived model of Indian villages in southern Mexico: Lacandon retain the idea in four trails leading from their hamlets – the fifth point – to the cardinal directions; Mayas recognize four Yum Balanobs, Fathers of Jaguars, guarding the four entrances to their settlements. Temples continued to be

Geometry and Architecture in the Americas, Fig. 7 Mayan Temple of Kulkulcan, Chichén Itzá, Yucatan. Profile and plan demonstrating how the temple was laid out in accordance with the eight-pointed star, the symbol of Venus (Based on drawings in Doczi, *The Power of Limits*)

G

rebuilt, some to terminate a bad cycle and start anew, and new ones erected as tombs for kings claiming descent from the gods themselves. In the ninth century many old kingdoms were crashing, while states across the Yucatan Peninsula and northern lowlands flourished. Chichén Itzá emerged in the eleventh century as the unchallenged ruler of the northern Maya. Analyses of three temples demonstrate the harmonic integration of sacred geometry with the structures and the importance of the eight-pointed star and Cosmic Cross.

Contrary to the Old World's equation of the planet Venus with the Mother Goddess, whose symbol was the eight-pointed star, Mayas identified it with their primary male creator Kulkulcan (Feathered Serpent and Rain God), whose symbol was the five-pointed star (actually half an eight-pointed one). Many Mayan buildings were aligned to track the star, especially at its last appearance on the western horizon – important for predicting its presumed heliacal rising 8 days later. Its heliacal rising, an unlucky omen, was tied to ritual warfare associated with the god

(Aveni, 1982, pp. 1–30; Schuetz-Miller, 2012b, pp. 378–380). Although the Temple of Kulkulcan at Chichén Itzá is known for its western staircase ending in snakeheads, when at sunset during the equinoxes the Feathered Serpent himself appears to undulate down the stairs, there is more than meets the eye. The eight-pointed star and the Cosmic Cross embedded in its structure are evident in Figs. 7 and 8. Its nine terraces are the nine levels of heaven, so cosmic space is transcended as one climbs to the top. Each staircase has 91 steps, totaling 364, and they share one common final step to account for the days of the year. Thus, one transcends time as well (Schuetz-Miller, p. 378; Van Kirk & Van Kirk, 1987, p. 33).

At the Temple of the Niches (Figs. 9 and 10), time is embedded in 365 niches rather than steps. Each side of the stairs is flanked by a ramp with a fret-like motif interpreted as abstract serpent or human vertebrae. The temple at the summit has five carved panels per side, above of which are friezes representing the sky. Zoomorphic motifs on the building include snake, coyote, and

jaguar – in some mythologies the brothers are identified as feline and canine (Schuetz-Miller, 2012b, pp. 380–3810).

Geometry and Architecture in the Americas, Fig. 9 Temple of the Niches, El Tajín. Yucatan. Profile and plan demonstrating how the temple was laid out in accordance with the eight-pointed star, the symbol of Venus (Analyses based on drawings in Doczi, *The Power of Limits*)

A final example of microcosm as macrocosm is the Temple of Quetzalcóatl at Teotihuacan (Figs. 11 and 12), which demonstrates the use of the eight-pointed star and halving of the square in its design. The city itself appears to have been planned with the Cosmic Cross as its model. Its eight square miles were laid out as a rectangular grid following a main north–south boulevard beginning with the Temple of the Moon (Moon Goddess, Guardian of the Underworld located in the north) at the north end and the Temple of Quetzalcóatl (son/consort of the Moon, associated with south in his rabbit avatar) at the south. The street was aligned to a slope of the sacred mountain, Cerro Gordo, three miles distant. Forming a Cosmic Cross was an intersecting east–west street that marked the setting of the Pleiades around May 18 at a time when the sun passes directly overhead and coincides with the first annual predawn appearance of the asterism. It further marked the setting of the sun on August 12, the anniversary of the beginning of the last great Mesoamerican calendar cycle, which according to some scholars began on 3114 BCE. Significantly, these and other alignment points are marked with Cosmic Crosses. The Pyramid of the Sun, between those of the

Moon and Quetzalcóatl, was built over a cave, suggesting it was the place of emergence from the previous four worlds of Aztec cosmology

Geometry and Architecture in the Americas,
Fig. 10 Temple of the Niches, El Tajín. Yucatan. Profile and plan demonstrating how the temple was laid out in accordance with the eight-pointed star, the symbol of Venus (Analyses based on drawings in Doczi, *The Power of Limits*)

(Aveni, 1977, pp. 3–9; Schuetz-Miller, 2012b, pp. 381–389; Stuart, 1995, pp. 5–35).

This study had looked at examples of monumental architecture in the Americas from its initial appearance in Peru about 3000 BCE to the period of the Spanish Conquest. It demonstrates the use of a system of pre-Euclidean geometry in their design that embedded the builders' worldview, represented by the eight-pointed star as the symbol of deity, and the Cosmic Cross as a symbol of both divinity and the quincunxial organization of the earth. It was a worldview and a simple geometry, requiring no mathematical skills, shared with the Old World where its use can be traced back into the Neolithic age. This early form of geometry, derived from astronomic observation, was sacred knowledge because it mirrored the celestial kingdom of the gods and ancestors. It was religious belief visualized, not mathematics. It ensured commensurable proportions, was adaptable to any standard of measurement, and was easily taught. Coupled with the rich symbolism of indigenous creation myths, it produced an integration of cosmic view with geometry the equal of any produced in the Old World.

Geometry in Africa

Paulus Gerdes

The *sona* tradition is a part of the heritage of the Tchokwe, Lunda, Lwena, Xinge and Minungo peoples that inhabit the northeastern part of Angola, and of the Ngangela and Luchazi peoples of southeastern Angola and Western Zambia. When the Tchokwe met at their central village places or at their hunting camps, they usually sat around a fire or in the shadow of leafy trees spending their time in conversation, illustrated by drawings in the sand. These drawings are called *lusona* (singular) or *sona* (plural).

Most of these drawings belonged to an old tradition. They referred to proverbs, fables, riddles, animals, etc., and played an important role in the transmission of knowledge and wisdom from one generation to the next.

Every boy learned the meaning and execution of the easier *sona* during the intensive schooling phase of the circumcision and initiation rites. The significance and creation of more difficult *sona* were known only by specialists, the *akwa kuta sona* (those who know how to draw), who transmitted their knowledge to their sons.

The designs have to be executed smoothly and continuously. In order to facilitate the memorization of their standardized ‘sona’, the drawing

experts used the following mnemonic device. After cleaning and smoothing the ground, they first set out with their fingertips an orthogonal net of equidistant points. Then one or more lines were drawn that 'embraced' the points of the reference frame. By applying their method, the drawing experts reduced the memorization of a whole drawing to that of mostly two numbers (the dimensions of the reference frame) and a geometric algorithm (the rule of how to draw the embracing line(s)).

The *sona* tradition vanished almost completely. Tentative designs have been made to try to reconstruct the mathematical knowledge of the drawing experts.

They considered symmetry and monolinearity (i.e. a whole figure made up of only one line) important. Note the example of a *lusona* that is monolinear and that displays a rotational symmetry of order 4 (Fig. 1).

They invented geometrical algorithms for the construction of classes of 'sona'. Figure 2 displays two monolinear drawings belonging to the same class and constructed in agreement with the

same algorithm (Fig. 3). Both drawings represent the marks left on the ground by a chicken when it is chased.

The drawing experts also invented a series of rules for the systematic construction of monolinear *sona*. They probably knew why the rules were valid: they could prove in one way or another the truth of the theorems that these rules expressed.

Figure 4 illustrates one such a rule. This rule serves for chaining monolinear patterns and has been applied four times in the Tchokwe representation of a leopard with five cubs (see Fig. 5).

Geometry in Chinese Mathematics

Jean-Claude Martzloff

The earliest evidence of a systematic organization of regular shapes reproduced on material objects found in China dates from the third millennium BCE or even earlier. Painted motifs displaying geometrical patterns such as symmetrical arrangements of triangles, lozenges, or circles have been found on pottery pieces unearthed at Banpo (near present-day Xi'an) and other archaeological sites. (Banpo (Pan-p'o) Neolithic dwelling site, one of the most important of its kind, located in the vicinity of Xi'an, south Shenxi, to the north of the present village of Banpo, on a hillock. It was discovered in 1953 while men were constructing the foundations of a plant. It belongs to the Yangshao culture (ca. 6000 BCE). It comprises the remains of the foundations of 45 huts, 200 silos, painted potteries, animal bones, farming and fishing tools, and a necropolis (more than 200 tombs and 37 funerary urns).) These designs demonstrate an early interest in spatial ordering and are perhaps at the origin of subsequent developments even though we are now unable to establish any continuity between prehistoric and historic Chinese mathematics. Nonetheless, several Chinese myths and legends attest that the plumb line, the compass, the carpenter square, and the gnomon (a post of standard height) were commonly used in Zhou China (1121–256 BCE). This last instrument, in particular, was considered so important that the

Chinese began founding their astronomical and calendrical conceptions on the determination of the length of gnomon shadows.

Chinese mathematical computations based on the gnomon have been preserved in several important sources from Chinese antiquity such as the *Huai Nan Zi* (The Book of the Prince of Huai Nan) and the ► [Zhoubi suanjing](#) (The Canon of Gnomon Computations from the Zhou Dynasty) (Cullen, 1996). (The prince of Huainan, Liu An, lived under the first half of the Former Han (~206–8), his grand father was Liu Bang (r. ~206 to ~196), the founder of the Han dynasty. The whole text of the *Huai Nan Zi* has been recently translated into French (Le Blanc and Mathieu, 2003).) In these sources, gnomons and their shadows are considered as sides of similar right-angled triangles and properties of similarity are applied to the determination of the height of the sun, at noon, above the flat earth. Later on, the same technique was generalized and used for the determination of earthly distances not directly measurable such as the depth of a well, the height of a mountain, or the distance of an island from the shore. Toward the end of the third century AD, these techniques were edited in algorithmic form in a book entitled *Haidao suanjing* (The Sea Island Computational Canon) (Fig. 1).

Haidao suanjing, one of the Ten Mathematical Manuals (*Suanjing shishu*) of the Tang dynasty (618–907), was composed much earlier by the famous Liu Hui (late third century AD) and commented upon by Li Chunfeng (640–670). From the beginning, it was considered a sequel to the *Jiuzhang suanshu*. Under the Tang dynasty (618–907), it was incorporated in the famous *Suanjing shi shu* mathematical collection composed of ten treatises, just after the *Jiuzhang suanshu*. It was also first officially printed under the Northern Song. None of these antique manuscripts and prints have been handed down to us and the present edition of the text is mainly the result of a late eighteenth-century compilation of incomplete Southern Song dynasty editions, together with excerpts of the text incorporated into the famous encyclopedia, *Yongle dadian* published under the reign of the emperor Yongle (1403–1407).

Geometry in Chinese Mathematics,

Fig. 1 A variant of the *Haidao* technique, taken from Problem IV-3 of the *Shushu juzhang* by Qin Jiushao (1248). The drawing explains the process of “measuring the width of stream from a steeply slanting bank” in order to construct a pontoon bridge in view of military operations (Libbrecht, 1973)

The *Haidao suanjing* is a very short treatise, composed of only nine problems, all concerned with the determination of inaccessible lengths. Word for word, its title means “Sea *hai* Island *dao* computational *suan* classic *jing*”; it should not be taken literally since only the first problem of the collection has really something to do with a sea island, while some others concern mountain distances, the depth of a well, the width of a river estuary. In a word, its real topic is topometry seen under the angle of various special examples, not maritime surveying. In fact, the title is only here to give an idea of what the book contains by alluding to the specific content of its first problem. It is a kind of mnemotechnic device, a reminder.

As for the problems, their textual structure is uniform, composed as they are in the tripartite form of, first, the statement of a little enigma, second the solving technique and last, the commentary. While the problems are rather realistic, the solving technique is announced in a general way and states the succession of arithmetical operations to be performed in order to obtain the answer from the known data of the text, irrespective of the special numerical values various elements are given in the statement of the problem. In sharp contrast with the commentaries of the *Jiuzhang suanshu*, the present one is not devoted to the rational justification of the sequences of calculations. Rather, they only give some specific details concerning the underlying arithmetic.

The statement and solution of the first problem are as follows:

Let a Sea Island be observed. Erect 1,000 *bu* (paces) apart two poles of the same height, three *zhang*, in such a way that both are aligned on an equal level. When moving back 123 *bu* from the front pole and looking from the ground up to the top of the island, the top end of the front pole lies in the alignment. When moving back 127 *bu* from the rear pole and looking from the ground up to the top of the island, the top end of the back pole lies again in the alignment.

Question Find the height of the island and its distance from the front pole?

Answer Height of the island 4 *li* 55 *bu*; distance from the front pole 102 *li* 150 *bu*.

In a quite different spirit, the Mohists – a sect of preaching friars from the fourth and third centuries BCE – approached geometry from a logical point of view and attempted to define the point, the circle, the square, space, and even parallelism (this last point is controversial). Certain of these definitions bear a striking resemblance to those found in Greek mathematics, particularly in Euclid’s *Elements*. Still, there are important differences between both approaches: the Mohist definitions do not concern a single science, geometry, but include optics, mechanics, and

economics. Moreover, the Mohists allow their definitions to incorporate familiar objects from the immediate human environment such as the sun, the bolt of a door, and other very concrete notions. More importantly, the grammatical structure of the Chinese language is such that objects and their properties are not distinguished in any way in the Mohist definitions cf. A. C. Graham, 1978.

Mohist logic did not arouse much interest and was never again studied in China; Chinese geometry developed without concern for geometrical definitions, let alone axiomatic-deductive constructions. But during the Han dynasty (206 BCE-AD 220) Chinese mathematical knowledge was for the first time separated from other domains and recorded in the *Jiuzhang suanshu* (Computational Prescriptions in Nine Chapters, also translated as Nine Chapters on the Mathematical Art). (Generally speaking, *shu* means “technique” or “art.” For example, in terms like *labanshu*, cerography (lit. the art of cerography), *yaoceshu* (lit. the art of measuring from afar) telemetry, *qieduanshu*, amputation (the art of cutting limbs), *fashu* magic arts, *guoshu* (lit. national arts), i.e., Chinese traditional martial arts and gymnastics, *jianshu*, swordsmanship, *jishu*, technology, *mimashu* (lit. the arts of secret codes) cryptography, *meishishu* (lit. the art of fine eating) gastronomy, *suanshu* (lit. the arts of calculation) arithmetic and sometimes mathematics too, *yinshuashu*, printing, *zhanxingshu*, astrology, *zhiwenshu*, dactylography, and so on. From this, the title *Jiuzhang suanshu* could be said to be “the arts of the nine chapters.” However, it is also a fact that the text of the *Jiuzhang suanshu* consists of a list of problems with their *shu*, i.e., their prescriptions – or receipts or “instructions” – which is precisely the special meaning of *shu*, in this context; these *shu*, receipts, are sometimes also called “procedures” in a rather anachronistic way, as if computer listings and algorithms were at stake here. The title *Jiuzhang suanshu* means exactly “the *shu* of the nine chapters,” i.e., “the receipts of the nine chapters” or the “computational prescriptions in nine chapters.”) Composed of 243 problems and almost as many prescriptive solutions

(*shu* = method, device, prescription, algorithm), this very influential manual was eventually revered as a kind of mathematical Bible, so that as late as the seventeenth century certain respected Chinese mathematicians considered that all imaginable problems and computational methods would necessarily be interpretable in terms of the traditional nine chapters of the *Jiuzhang suanshu*.

In fact, the geometry of the *Jiuzhang suanshu* is not precisely an autonomous body of knowledge and consists essentially in a threefold compilation of problems pertaining to planimetry, stereometry, and right-angled triangles. Planimetry is included in the first chapter of the *Jiuzhang suanshu* and comprises a collection of formulae needed to compute the area of fields in the form of squares, rectangles, triangles, trapezia, circles, rings, and segments of circles. Stereometry is found in the fourth and fifth chapters and concerns the computation of volumes or capacities of cubes, parallelepipeds, pyramids, spheres, as well as that of various prisms, dikes, moat walls, ditches, excavations, and cylindrical or prismatic grain silos. Problems on right-angled triangles are found in the last chapter of the *Jiuzhang suanshu* and bear upon Pythagoras’ theorem, where some dimension of a right-angled triangle is sought, given simple algebraic combinations of other dimensions (such as the sum of its base and hypotenuse, its area, and so on). Lastly, the determination of the side and diameter of a square and a circle, respectively, inscribed in the same right-angled triangle are also considered. Nongeometrical subjects are also dealt with in the same chapters (for example, fractions in the first chapter, square and cube roots in the fourth). In addition, various concerns (units of measurement, for example) frequently interfere with the geometrical aspect of problems, so that they seem highly realistic at first sight. In reality, most of them are artificial, since the situations they describe are often the inverse of what would naturally occur in real life: one is often asked to determine the dimensions of a figure given its area or its volume. On the whole, these problems are strikingly similar with those found in the *Suanshu shu* (*Book of arithmetic*) an arithmetical

manual written on ► [bamboo](#) strips from ca. 186 B.C., found in 1983–1984 in a tomb of a Chinese nobleman from the Western Han Dynasty in a site near Zhangjiashan, Jiangling country, Hubei province.

Given that problems on planimetry, stereometry, and right-angled triangles quite similar to the above ones are also well represented in the known corpus of Babylonian mathematics, it would seem that there is no essential difference between Chinese and Babylonian geometry. That is not the case, however, for on the one hand, the solutions of Chinese problems are practically never stated using particular numbers but rather general formulations, and on the other hand, certain Chinese mathematicians have felt the need to justify geometrical results. Remarkably, these justifications would appear quite correct and even accessible to informal proofs in the eyes of modern mathematicians not at all acquainted with Chinese mathematics.

Chinese proofs of geometrical results have been preserved in various commentaries on the *Jiuzhang Suanshu* composed between the third and the seventh century AD by Liu Hui (fl. ca. end of the third century), the author of most of them, ► [Zu Chongzhi](#) (429–500), a famous astronomer and mathematician known for his approximation $\pi = 355/113$, and Li Shunfeng (602–670), an astronomer and compiler of the *Suanjing shi shu* (Ten Computational Canons), a collection of mathematical manuals representative of Chinese mathematical knowledge from the origins to the seventh century. As may be expected, the commentaries do not focus on mathematics alone, but concentrate also on many other aspects of problems needed to understand their original context and pertaining to history, geography, philology, pedagogy, and philosophy. The commentaries are thus intrinsically nonhomogeneous. In their turn, the proofs themselves are often interspersed with numerous digressions and are no more homogeneous than the rest of the commentaries they are imbedded in. Moreover, they frequently rely on all sorts of results (Pythagoras' theorem, for example) not yet proved when they were first used. Reasoning is thus neither constrained by formal modes of

presentation nor by restrictions on what is admissible and what is not. In particular, numerical computations are liberally used, even when strictly speaking they would not necessarily be needed. More surprisingly however, but probably for mnemotechnical reasons, most proofs are formulated in a terse language; deductions are only suggested and based on a limited number of heuristic principles whose formulation is also extremely concise and which are used over and over again.

One of these heuristic principles can be described as a generalized form of the so-called “Cavalieri's principle” (named by analogy with a famous proposition found in Bonaventura Cavalieri's *Geometria Indivisibilibus*; Bologna 1635). (The original text of Cavalieri's *Geometria Indivisibilibus* is wholly accessible from the Biblioteca Digitale IMSS (Istituto e Museo di Storia della Scienza, Firenze) (<http://www.brunelleschi.imss.fi.it/bd/>).)

In its Chinese version, this principle is limited to solids and states that when the areas of the plane sections of two solids always have the same proportion between them, their volumes also have the same proportion. According to another heuristic principle, when a figure is dissected into several pieces as if it were a puzzle, and when the pieces are adequately reassembled, the area (or the volume) of the initial and final figures is equal. This principle is used with standard colored pieces (*qi*) but these are not necessarily the equivalent of concrete pieces of some puzzle since their number is sometimes infinite and involves the idea of carrying the process to the limit. This is the case, for example, in the derivation of the volume of the pyramid, in a way which reminds us of Euclid's proof of the volume of the pyramid (*Elements*, book 12, prop. 5), as the mathematician and historian of mathematics B. L. van der Waerden has suggested (“Liu [Hui]'s proof is very similar to that of Euclid, and it is based on just the same division of a tetrahedron into two prisms and two smaller tetrahedra” (van der Waerden, 1983, pp. 204, 202ff)). This dissection technique is so productive that its usage extends beyond the bounds of geometry. Very often, properties that

we would call “algebraic” (especially when the equivalent of equations comes into play) are manipulated figuratively by means of dissections, so that algebraic relations are directly visualized without any recourse to discursive reasoning or even to particular computations.

As numerous quotations from classical texts (such as Confucius’s *Analects*, the *Yijing* (I Ching, Book of Changes) or Zhuangzi’s works) found in the commentaries on the *Jiuzhang suanshu* suggest, this approach largely depends on Confucian and Daoist ideas. (Also known as *Zhuangzhou* (ca. 370–300 BCE), this Daoist philosopher from the Warring States period is the author of the *Zhuangzi* and can be considered as the master of irrationalism.) According to the Confucian conception, when presenting new knowledge, all the details should not immediately be revealed to students in order to oblige them to make efforts which would result in a deeper understanding. Similarly Zhuangzi favored conciseness of expression, but for a very different reason: he believed that, as sophisms show, discursive reasoning is intrinsically limited and therefore any efficient access to knowledge should necessarily include all imaginable modes of apprehension of reality and not only discursive reasoning. On the whole, these conceptions induced defiance toward modes of reasoning based on language alone; hence the recourse to nonlinguistic modes of communication such as those based on computations or figurative techniques. Still it remains possible that the *Jiuzhang suanshu* and its commentaries are also the result of various other influences which did not necessarily originate in the Chinese world. In this respect it should be noted, for example, that Archimedes and other Greek mathematicians already used equivalents of Cavalieri’s principle many centuries before the advent of the *Jiuzhang suanshu* and its commentaries. Dissections are also attested in antiquity, particularly in Archimedes’ *Stomachion* and even more strikingly, the Chinese proof relating to the volume of the sphere relies, among other things, on the knowledge of the fact that the volume of a solid defined by the intersection of two orthogonal cylinders inscribed in the same cube is equal

to two-thirds of the volume of the cube, a result explicitly stated in Archimedes’s *Method of Mechanical Theorems for Eratosthenes* and in Heron of Alexandria’s *Metrika*. (Cf. E. J. Diksterhuis (1987). The *Stomachion*: “This is a kind of game, played with ivory pieces in the form of simple planimetric figures, the object being to fit these various bits together in such a way that various shapes of human beings, animals or different objects were imitated.” Note that this conclusion is solidly based on quotations taken from several classical authors. In other words, the *Stomachion* is a kind of puzzle in use in classical antiquity, more than 2,000 years before the first mention of the tangrams in China, first in the seventeenth century, and above all at the beginning of the nineteenth century.)

After the seventh century, the Chinese repertory of planimetric and stereometric formulae was continuously enriched. Among the most interesting results from this period, one must cite Hero’s formula for the computation of the area of a triangle given its sides, which was published in Qin Jiushao’s *Shushu juzhang* (Mathematical Works in Nine Chapters, 1247). (On this the indispensable reference always remains U. Libbrecht’s outstanding masterpiece, *Chinese Mathematics in the Thirteenth Century, the Shu-shu chiu-chang of Ch’in Chiu-shao*. Cambridge, Massachusetts: MIT Press, 1973.) Despite its title, this work is very different from the *Jiuzhang suanshu* and is better known for its study of the “Chinese remainder problem” (simultaneous congruences) and its algebraic developments. After the seventh century however, and until the seventeenth, geometrical proofs were never again recorded in Chinese mathematical books. This fact perhaps has something to do with the remarkable development of Chinese algebra which took place during the Song and Yuan dynasties, for algebraic computations have the capacity to generate new results by means of mere computations. Nevertheless, we must admit that we absolutely do not know why some eminent Chinese like Liu Hui or ► [Zu Chongzhi](#) became interested in mathematical proofs endowed with a rather strong Greek flavor,

from the triple point of view of its methods, contents, and results, during a short interval of time, limited to a few centuries, and in a context where Chinese geometry was previously limited to trivial or semitrivial results (such as $\pi = 3$ in the *Jiuzhang suanshu*). (Clavius, *C. Euclidis Elementorum libri XV, Accessit XVI de Solidorum Regularium cuiuslibet intra quodlibet comparatione*. Coloniae (Köln), 1591. Cf. P. M. Engelfriet, *Euclid in China. The Genesis of the First Translation of Euclid's Elements Books I-VI (Jihe yuanben: Peking 1607), and Its Reception up to 1723*. Leiden: Brill, 1998. Review: J. -C. Martzloff. *Euclid in China. Monumenta Serica* 47 (1999): 479–488.)

At the beginning of the seventeenth century, the Chinese became aware of axiomatic-deductive modes of reasoning when, in 1607, the first six books of Christopher Clavius's commentary on Euclid's *Elements* were translated into Chinese by the Jesuit missionary Matteo Ricci (1552–1610) and Xu Guangqi (1562–1633) under the title *Jihe yuanben* (*jihe* = geometry or quantity and *yuanben* = elements, so that *Jihe yuanben* means either “*Elements of Geometry*” or “*Elements of the Measure of Quantities*”) – here, the reader will perhaps deem this story unbelievable. Why, from the very beginning, were Jesuits in China more interested in translating Euclid into Chinese rather than the Bible, papal bulls, catechisms, and other religious texts much more in keeping with a missionary activity? In fact, the answer has to do with the Jesuit educational policy in the context of the Catholic counter-reform. In their *Ratio studiorum* the Jesuits stress the importance of deductive mathematics because of its strong connection with theology: mathematics are extremely important because the kind of knowledge they provide depends both on dogmatic assertions – axioms and postulates – and deductive reasoning leading to truth and certainty. In other words, teaching mathematics to the Chinese was felt like the first and necessary step toward the propagation of religious truths. (Cf. Romano Antonella, *La Contre-Réforme Mathématique: Constitution et Diffusion d'une Culture Mathématique Jésuite à la Renaissance*

(1540–1640). Paris: École Française de Rome, 1999.) Xu Guangqi was a Christian convert and influential high official responsible for the reform of Chinese astronomy undertaken from 1630 onward on the basis of imported European knowledge. It has often been noted that some Persian or Arabic version of Euclid's *Elements* had already reached the Chinese imperial library three centuries earlier, during the Mongol domination of China, but there exists no evidence of any Chinese translation made during that period, and no trace of influence on subsequent Chinese mathematics has ever been detected.

At first, the new geometry was not much studied save by a few converts and Chinese students of Western astronomy who served the Jesuits at the imperial bureau of astronomy. However, as time went on, many Chinese scholars impressed by the successes of European sciences (especially mathematical predictions of celestial phenomena such as eclipses of the sun and calendrical computations) began to study the *Elements* seriously. The majority of these scholars considered that Euclid stood at the very basis of the new Western knowledge. At the same time they also believed that once properly reinterpreted, the results of the *Elements* were the same as those of their nine mathematical chapters; they also thought it desirable to dissociate the content of the *Elements* from its form. Far from representing the very model of logical clarity and the universal basis of all true knowledge, the formal structure of argumentation was judged inappropriate and even noxious. A textual recasting (of the *Elements*) not only affected demonstrations but also geometrical figures, and mathematicians of the first order such as Mei Wending (1633–1721) did their best to dissociate geometrical figures from the demonstrations to which they were attached. Thus, they sometimes redrew figures so as to make the corresponding theorems directly visible. Taking as it were the appearance of “monstrations,” demonstrations changed of nature through the intermediary of tangible figurative representations. At the same time, this major transformation of Euclidean space was accompanied by an extensive “numerization” of geometry. Whereas, in their underlying logic,

Euclid's *Elements* dealt with intrinsic properties of numbers in general, without ever quoting any precise number, even when questions of area and volume were at stake, Chinese geometers made massive use of explicitly mentioned particular numbers, computed if need be with a high degree of precision (Martzloff 1993–1994, pp. 71–72).

Such reactions against the *Elements* were also fairly common in Europe during the seventeenth century, but, in sharp contrast with what happened in China, these European reactions (which often went hand in hand with the rejection of Aristotelianism and scholasticism) were never powerful enough to dominate the mathematical scene, except perhaps in elementary education. In fact, during the seventeenth and eighteenth centuries, China was dominated by a strong reaction against all sorts of speculative reasoning prevalent during the preceding centuries which was designated as the source of Chinese decline. Consequently, numerous scholars advocated the development of concrete sciences (*shixue*), i.e., of applied sciences whose usefulness could be tangibly demonstrated by an increased social welfare. Thus, if mathematics were to be used at all, computational results had to be expressed in the form of easily understandable instructions. In this respect, syllogisms like those of the *Elements* were particularly difficult to use, inasmuch as they also involved numerous repetitions, a characteristic which was also contrary to the canons of Chinese literary composition. In addition, certain critics also wrote that Euclid's *Elements* were written in a cryptic language devised purposefully to obscure simple mathematical results. Many scholars found still another reason to defy geometry; they believed – not without basis – that they had detected an essential similarity between formal discourses typical of the rhetoric of geometrical demonstrations and the scholasticism of the theological speculations widely diffused by the European missionaries. Hence there was a rejection of forms of expression which tended to speculative form.

These ideas remained unchallenged in China until the end of the nineteenth century, but if axiomatic-deductive reasoning was never studied

as such during that period, geometrical results were nevertheless taken seriously as early as the second half of the seventeenth century. In particular, a famous mathematician Mei Wending developed at length the computational aspect of the stereometry of regular and semiregular polyhedrons on the basis of a very incomplete description of these that he had found in the *Celiang quanyi* (Complete Treatise on Measurements), a manual based on Clavius's *Geometria practica* and translated into Chinese ca. 1635. Others tried to recast to content of the *Elements* into the mold of the nine chapters of the *Jiuzhang suanshu*. From the end of the seventeenth century, new Chinese and Manchu translations of the *Elements* were realized under the patronage of the Kangxi emperor. These were all given the same title as the former translation of the *Elements* published a century earlier. However, they were very different from Clavius's commentary since they were all essentially based on Father Gaston-Ignace Pardies (1636–1673) (Ziggelaar, 1971). *Elements de géométrie*, a French manual very different from Euclid's initial text and intended for the teaching of geometry in Jesuit colleges (Ziggelaar, 1971). Pardies' manual (first published in 1671) was so popular that it remained in use in Europe during a whole century and was translated into several European languages. The new translations of the *Elements* all remained in manuscript form, but these eventually gave birth to a final text which was eventually incorporated into a famous mathematical encyclopedia published by imperial order at the end of Kangxi's reign, the *Shuli jingyun* (Collected Essential Principles of Mathematics, 1723). Whereas this encyclopedia remained in use in China for two centuries, the not yet translated part of the first translation of the *Elements* was carried out between 1852 and 1856 by Alexander Wylie (1815–1887) (Fig. 2), a British Protestant missionary, and ► [Li Shanlan](#) (1811–1882), a renowned translator of Western manuals on astronomy, mathematics, botany, and other scientific subjects. This time, the translation was not based on Clavius' commentary but on Heury Billingsley's English translation of Euclid's *Eleane eats* released in 1570 in

Geometry in Chinese Mathematics, Fig. 2 Alexander Wylie

17 books. (Cf. Xu Yibao, “The First Chinese translation of the last nine books of Euclid’s *Elements* and its source” *Historia Mathematica*, 2005, Vol. 32, no. 1, pp 4–32.) After 1760, other elementary Western textbooks on geometry, which have been forgotten since, were again translated into Chinese.

After the 1911 revolution, Chinese mathematics was never again studied for scientific purposes (except by historians) and China gradually made its way into the international mathematical community. Nowadays, there is of course no distinction between geometry developed in China and in other countries.

Geometry in India

George Gheverghese Joseph

An examination of the earliest known geometry in India, Vedic geometry, involves a study of the *Śulbasūtras*, conservatively dated as recorded between 800 and 500 BCE, though they contain knowledge from earlier times. Before what is conventionally known as the Vedic period (ca. 1500–500 BCE), there was the Harappan civilization dating back to the beginning of the third millennium BCE. Even a superficial study of the Harappan cities show its builders as extremely capable town planners and engineers requiring fairly sophisticated knowledge of practical geometry. An interesting conjecture has been suggested by a drawing on a seal found from Harappa (ca. 2500 BCE): was there an awareness then that the area of a polygon inscribed in a circle approaches the area of the circle as the number of sides of the polygon keeps increasing? This is the basic idea behind techniques that were developed for the mensuration of the circle in a number of mathematical traditions including Indian.

The *Śulbasūtras* are instructions for the construction of sacrificial altars (*vedi*) and the location of sacred fires (*agni*) which had to conform to clearly laid down instructions about their shapes and areas if they were to be effective instruments of sacrifice. There were two main

types of ritual, one for worship at home and the other for communal worship. Square and circular altars were sufficient for household rituals, while more elaborate altars whose shapes were combinations of rectangles, triangles, and trapezia were required for public worship. One of the most elaborate of the public altars was shaped like a giant falcon just about to take flight (*Vakraprakṣa-śyena*). It was believed that offering a sacrifice on such an altar would enable the soul of the supplicant to be conveyed by a falcon straight to heaven (Fig. 1).

It is clear that if in the construction of larger altars they had to conform to certain basic shapes and prescribed areas or perimeters, two geometrical problems would soon arise. One is the problem of finding a square equal in area to two or more given squares; the other is the problem of converting other shapes (for example, a circle or a trapezium or a rectangle) into a square of equal area or vice versa. The constructions were achieved through a judicious combination of concrete geometry (in particular what would be known today as the principle of dissection and reassembly), ingenious algorithms, and the application of the so-called Pythagorean theorem. The essence of the dissection and reassembly method involves two commonsense assumptions. The first is that both the area of a plane figure and the volume of a solid remain the same under rigid translation to another place. The second says that if a plane figure or solid is cut into several sections, the sum of the areas or volumes of the sections is equal to the area or volume of the original figure or solid. The reasoning behind this approach was very different from that behind Euclidean geometry, but the method was often just as effective, as shown in the Indian (and Chinese) “proofs” of the Pythagorean theorem.

In the *Kātyāyana Śulbasūtra* (named after one of the authors) the following proposition appears: “The rope (stretched along the length) of the diagonal of a rectangle makes an (area) which the vertical and horizontal sides make together.” (2.11). Using this version of the Pythagorean theorem, the *Śulbasūtras* show how to construct both a square equal to the sum of two given

Geometry in India, Fig. 1 The first layer of a Vakrapaksa-syena altar. The wings are made from 60 bricks of type “a,” and the body, head and tail from

50 type “b,” 6 of type “c” and 24 type “d” bricks. Each subsequent layer was laid out using different patterns of bricks with the total number of bricks equaling 200

squares and a square equal to the difference of two given squares. Further constructions include the transformation of a rectangle (square) to a square (rectangle) of equal area and of square (circle) to a circle (square) of approximately equal area. The constructions “doubling the square” and “squaring the circle” lead naturally to devising algorithms for the square root of 2 and other numbers, for implicit estimates of π , and for constructing similar figures in required proportions of a given figure.

The composers of the *Śulbasūtras* made it clear that their work was not original but could be traced to earlier texts, notably the *Samhitās* and the *Brāhmaṇas* of which the most relevant text, *Śatapatha Brāhmaṇa*, is at least 3,000 years old. In spite of its obscurities and archaic character the text is valuable for an early discussion of the technical aspects of altar construction. The instructions given in *Śatapatha Brāhmaṇa* (X.2.3.11–14) for constructing a falcon-shaped altar consisting of 95 layers of bricks are as follows:

$$\text{Area of the body (Atman)} = 56 + \frac{12}{7} \sqrt{56};$$

$$\begin{aligned} \text{Area of two wings} = & 2(14) + \frac{3}{7} \sqrt{14} \\ & + \left(\frac{1}{5}\right) \left(\frac{1}{7}\right) (3) (\sqrt{14}); \end{aligned}$$

$$\text{Area of tail} = 14 + \frac{3}{7} \sqrt{14} + \left(\frac{1}{10}\right) \left(\frac{1}{7}\right) (3) (\sqrt{14}).$$

The total area is about 116 square *purushas*, which is an over-estimate of the required 101.5 square *purushas*, arising in part from a rounding off error involved in taking 14 rather than $13 + 8/15$.

A major strand running through the history of Indian geometry and also providing the main motivation for the development of the subject was a recognition of the impossibility of arriving at an exact value for the circumference of a circle given the diameter (i.e., the incommensurability of π). A passage in Āryabhaṭa’s *Āryabhaṭīya* (AD 499) – Verse 10 of the section on *Gaṇita* – reads:

Add 4 to 100, multiply by 8, and add 62,000. The result is *approximately* the circumference of a circle whose diameter is 20,000. (Giving an implicit value of 3.1416 for π . This was the most accurate estimate for π known at that time. About 600 years earlier (ca. 150 BCE), there was an implicit estimate of π as the square root of 10 in a Jaina text called *Anuyoga Dwāra Sūtra*.)

It was the word “approximately” that gave food for thought to commentators of Āryabhata’s work from ► **Bhāskara I** (ca. AD 600) to Nīlakanṭha (b. AD 1445). The first formal proof of the transcendental nature of π was given by the Swiss mathematician Lambert in a paper to the Berlin Academy in 1671. However, about 150 years earlier, Nīlakanṭha’s commentary on *Āryabhaṭīya* contained the following statement:

Why is only the approximate value (of circumference) given here? Let me explain. Because the real value cannot be obtained. If the diameter can be measured without a remainder, the circumference measured by the same unit (of measurement) will leave a remainder. Similarly the unit which measures the circumference without a remainder will leave a remainder when used for measuring the diameter. Hence the two measured by the same unit will never be without a remainder. Though we try very hard we can reduce the remainder to a small quantity but never achieve the state of ‘remainderlessness’. This is the problem. (Adapted from Sarasvati Amma 1979)

Once the incommensurability of π was accepted, the approach of the Indian mathematician was to obtain as accurate a value of this quantity as possible, and the strategy to be followed was expressed thus by Śaṅkara Variyār and Nārāyana Kriyākramakarī (ca. 1550):

Thus even by computing the results progressively, it is impossible theoretically to come to a final value. So, one has to stop computation at that stage of accuracy that one wants and take the final result arrived at ignoring the previous results. (Adapted from Sarma 1975)

The major breakthrough came from the revolutionary idea, most probably that of Mādhava (ca. 1340–1425), that it was possible to obtain an infinite series whose sum would be exactly equal to π and that an increasingly close rational approximation of the quantity could be obtained by taking partial sums successively of higher order. While the question of the slow

convergence of this series was not explicitly discussed, the need for increasing rapidity of convergence was recognized and some remarkable corrections to be applied to truncated series were deduced. The work on infinite series for circular functions provided an impetus to derivation of other infinite series for trigonometric functions, namely arc tangent, sine, and cosine series. Often inductive reasoning (and intuition) built upon geometrical representation helped them to discover these results, but the proof of these results can withstand any rigorous criterion applied to it today. An implicit estimate for π based on infinite-series expansion given by Mādhava around 1,400 is correct to 11 decimal places.

Another area of geometry in which the Indian contribution was significant was in the study of the properties of a cyclic quadrilateral. In the *Brāhma Sphuṭa Siddhānta*, ► **Brahmagupta** (b. AD 598) gives these results:

1. The area of a cyclic quadrilateral is given by the product of half the sums of the opposite sides, or by the square root of the product of four sets of half the sum of the sides (respectively), diminished by the sides.
2. The sums of the products of the sides about the diagonal should be divided by each other and multiplied by the sum of the opposite sides. The square roots of the quotients give the diagonals of a cyclical quadrilateral.

The derivations of these results are first referred to in a tenth-century commentary on Brahmagupta’s work, but find their full expression in the sixteenth century Kerala text *Yuktibhāṣā* by Jyeṣṭhadeva. This makes use of Ptolemy’s theorem that in a cyclic quadrilateral the product of the diagonals is equal to the sum of the products of two pairs of opposite sides.

Notable extensions in this area are contained in Nārāyana Pandita’s *Gaṇita Kaumudī* in the fourteenth century and Parameśvara’s *Līlāvati Bhāṣya*, a detailed commentary on Bhāskaracharya’s *Līlāvati*. In the latter is found a new rule for obtaining the radius of the circle in which a cyclic quadrilateral is inscribed.

The great interest in the cyclic quadrilateral in Indian mathematics arose from the fact that it was an important device for deriving a number of important trigonometric results which were in almost all cases used in astronomy.

In India geometry never became idealized in the way it did in Greece. Geometry was largely concrete and empirical in character. It did, however, have an algebraic character which is best seen in the genesis of trigonometry there. Because of their geometric emphasis, the Greeks used chords in their astronomical calculations, whereas the Indians developed the notion of sines and versines (i.e., $1 - \cos$ of an angle) as early as AD 500. Āryabhata was perhaps the first Indian astronomer to give a special name to these functions and draw up a table of sines for each degree. Approximation formulae were developed for these functions, culminating in the construction of sine tables in Kerala during the fifteenth century where the values in almost all cases are correct to the eight or ninth decimal place, a remarkable degree of accuracy.

Geometry in Islamic Art

Carol Bier

Center for Islamic Studies, Graduate Theological Union, Berkeley, CA, USA

The Textile Museum, George Washington University, Washington, DC, USA

Geometric patterns in two and three dimensions comprise one of the key characteristics of arts and architecture of the Islamic world in many cultural traditions from the central Islamic lands of the Middle East to Spain, India, Indonesia, and sub-Saharan Africa (Bloom & Blair, 2009; Broug, 2013; Ettinghausen, Grabar, & Jenkins-Madina, 2001; Gerdes, 1999; Hillenbrand, 1994, 2009). Although geometry is present, either by conscious human choice in design or as an inherent feature of architectural production in all

cultures, it seems to have assumed a much higher significance in Islamic centers of civilization (Grabar, 1992). Often attributed to a proscription against figural images, this interpretation is not borne out historically with reference to palace wall painting, ceramics, ivory, woodwork, and book illustration rich with pictorial narrative. There are, indeed, other more rational explanations for the emphasis on geometric figures (Allen, 1988; Freedberg, 1989; Belting, 2011) as well as many unanswered questions (Grabar, 1992). From the eleventh century throughout the central Islamic lands, the clustered and segmented vaults of *muqarnas* were used to effect spatial transitions for domes, vaults, and arches, or as a corbel to support balconies and cornices (Bloom, 1988; Tabbaa, 1985), exhibiting elaborations in succeeding centuries (Al-Assad, 1995; Golombek & Wilber, 1988). Simultaneously, one may trace the development of patterns in the plane from the empirical juxtaposition of geometric shapes to more complex arrangements with networks of intersecting polygons, which suggest direct relationships to academic studies of geometry in the Euclidean tradition (cf. Allen, 2004, who argues against such an interpretation). Yet precise intersections between the histories of architecture and mathematics have not been fully elucidated (Berggren, 2008; Bier, 2012; see also, Necipoğlu, 2015). The text of Abū'l Wafā' al-Būzjānī (d. 998) suggests direct links including conversations among artisans and mathematicians, leaving much to speculation (Chorbachi & Loeb, 1992; Özdural, 1995, 2000; see also Sarhangi, 2008b).

Geometry in the Service of Religion: Kaaba, Qibla, Hajj, Awqaf, Salat, and Khatt

Science, mathematics, and material culture also intersect in the service of Islam – in particular, the construction of astrolabes requires carefully placed markings that register a projection of three-dimensional space in two dimensions to find the direction and distance to Mecca through astronomical measurements and calculations

from a specific place (King, 1999). In architecture, geometrical considerations impact determination of *qibla* (the direction toward the Kaaba in Mecca), which orients both prayer space and worshipper for prayer, *salat*. The qibla wall of a mosque or prayer hall is often marked with an ornamented *mihrab*, or niche, which frequently incorporates geometric patterns and forms. And the times of prayer, *awqaf*, are based upon the sun's position. The Kaaba itself (Arabic “cube”), which antedates Islam, is conceptually cubic in form, associated with rituals of circumambulation that comprise part of *hajj*, the pilgrimage prescribed for Muslims in the Qur'ān, and rites outside the formal *hajj* season (*'umra*). Similar practices that entail circumambulation are associated in some instances with local shrines and tombs throughout the Islamic world (Mawani, 2016). Because Muslims believe the Qur'ān to have been revealed in Arabic, both language and script (*khatt*) have assumed elevated status within Islamic cultures, a status that contributed to the development of elaborate calligraphic forms often based upon systems of geometric proportion.

Patterns in the Plane: Symmetry and Periodicity

The presence of geometry is evident in the earliest Islamic monuments, including the octagonal plan and prismatic structure of the late seventh-century Dome of the Rock in Jerusalem (Grabar, 2006). Geometric patterns in the plane or radial symmetry appear extensively in floor mosaics, carved stucco, and wall ornaments at Khirbat al-Mafjar near Jericho (Hamilton, 1959), drawing upon the Late Antique artistic heritage of the late Roman, Byzantine, and Sasanian empires. In the ninth century, periodic patterns in the plane exhibit symmetry in the palaces at Samarra and in other more distant Abbasid centers such as Balkh, with similarities of style noted in architectural stucco, woodwork, ceramics, as well as in objects of other materials, such as rock crystal, inlaid wood, and ivory (Ettinghausen et al., 2001). All such periodic patterns have visible or

[metmuseum.org](http://www.metmuseum.org)

implied square, rectangular, triangular, rhombic, or hexagonal grids and utilize symmetries of reflection, translation, glide reflection, and rotations of orders 2, 3, 4, and 6. At Nishapur in northeastern Iran, a wall panel in carved stucco (Fig. 1) exhibits a plane pattern with overlapping, interlacing hexagons, each spatial unit of the tiling filled with vegetal ornament that is also a characteristic of an Abbasid style. In these early examples of periodic patterns in Islamic art, there is a notable absence of pentagons and decagons, which offer geometric challenges in the spatial dimension. Unlike other regular polygons (equilateral triangles, squares, and hexagons), their interior angles are not factors of 360° . An early complex interlaced pattern with local tenfold rotations set within an implied rhombic grid, as reconstructed by Bonner (Fig. 2a), appears on the stellated octagonal tower of Mas'ud III in Ghazna (Fig. 2b), dating to the late eleventh or early twelfth century (Bonner, 2015). And a pattern with concentric decagrams (ten-pointed stars), also set within an implied rhombic grid, may be discerned in the tympanum of the Gonbad-e Alaviyyan in Hamedan in western Iran (Fig. 3). The use of decagons and decagrams in periodic patterns is highly unusual and may indicate a major achievement in the utilization of geometry for architectural ornament, overcoming

the intransigence of pentagons and decagons to tessellate the plane (see also Nava'i (2012) and Sarhangi (2013a)).

Forms and Patterns Based upon Divisions of the Circle

In Spain, three domed chambers in front of the *mihrab* of the Great Mosque of Cordoba, dating from an extension of the building in the mid-tenth century, exhibit the earliest evidence of ribbed domes, constructed using four pairs of parallel ribs, which interlace to form an octagon and eight-pointed star (Fuentes González & Huerta, 2010). The earliest appearance of a pentagon seems to be in the north dome of the Masjid-e Jomeh, Isfahan, dated to 1088–1089 (Fig. 4), possibly to be associated with the mathematician, Omar Khayyam (Özdural, 1995, 1998). In addition, there are two patterns having local fivefold symmetries (convex and concave polygons) that also appear in the north dome chamber in recessed tympana in the transition zone below the dome.

With a circular or polygonal plan, numerous prismatic tomb towers built of fired brick were constructed in Iran and neighboring lands during the ninth through twelfth centuries. The tradition

continues with great architectural variation (Hillenbrand, 1994), including the extensive use of glazed bricks and ceramic mosaic, which led to

the introduction of tiles. The design of these mausolea begins with a center point and circle; the circle may then be divided into equal segments.

Geometry in Islamic Art, Fig. 4 Isfahan, Iran. Masjid-e Jomeh. North Dome (Gonbad-e Khaq), with central pentagon. 1088–89 (Josephine Powell photograph, Courtesy of Special Collections, Fine Arts Library, Harvard University)

Early examples include the monuments at Radkan, Demavend, Lajim and Kharraqan in Iran, and Bust in Afghanistan. The most common form is an octagonal prism with a variety of conical or polyhedral roofing arrangements (Ashkan & Ahmad, 2012). Several different architectural structures also suggest experimentation with geometry and form; examples include the unique tapering

stellated decagonal tower at Gonbad-e Qabus (dated 1006–1007) with its smooth conical roof and the cubic “tomb of the Samanids” in Bukhara (Fig. 5), with its elaborately reticulated brickwork arranged to display decorative patterns.

Broug (2013, Fig. 1, pp. 21–24) clearly explains pattern families derivative of divisions of the circle into four or eight segments, three or six segments, and five segments in Islamic geometric patterns. In analyzing plane patterns in Islamic art, Bonner (2015) amplifies these categories based upon an elaboration of obtuse, median, or acute angles at points of intersections of bisected lines; he also adds a category for more complex patterns with two-point sharing, introduced in the late twelfth century.

Typically many different geometric patterns appear on a single monument. From the early Islamic period until the mid-eleventh century, such two-dimensional patterns seem to be composed by design algorithms, whether executed in stone or glass mosaic (as in the Dome of the Rock and at Khirbat al-Mafjar) or in brick (as in Bukhara, Demavend, Isfahan, and elsewhere). A unit is repeated according to an organizing principle (today identified as a symmetry group), which results in a pattern. The geometry is emergent. For example, ornamental brickwork relies upon bricks being set in different orientations (vertical and horizontal) or bricks used in proportions of 1:2:3, as at Demavend (Fig. 6),

Geometry in Islamic Art, Fig. 5 Bukhara, Uzbekistan. Tomb of the Samanids, exterior view of articulated brickwork. Tenth century. (Courtesy: © Frank Harold, 1999, <https://depts.washington.edu/silkroad/cities/uz/bukhara/bukhara.html>)

in the earlier tower at Kharraqan (dated 1067), and in blind niches at Gonbad-e Surkh at Maragha. Sometimes the bricks are set with mortar that appears to be intentionally set back, thereby more clearly articulating algorithmic patterns through the play of sunlight and shadow, projection, and recess, as in Bukhara, and on the facades of the two tomb towers at Kharraqan in western Iran.

By the late eleventh century, there seems to be a change, first evident on the entry facades at Kharraqan (Fig. 7) and then on the façade of the Gonbad-e Surkh (Fig. 8), indicated by bricks having been cut to size to create different patterns. Despite its out-of-the-way location off the Hamadan-Qazvin road, the later tomb tower at Kharraqan (dated 1093) provides the earliest

evidence for the introduction of glazed ceramic elements (Pickett, 1997; Stronach & Young, 1966). In the succeeding 100 years, the use of glazed architectural ceramics increased dramatically (Wilber, 1939). Blue-glazed bricks, using a copper colorant for the glaze, were used extensively to cover the long narrow triangular facets of tall pyramidal roofs with polygonal bases, which reflected sunlight from every direction – as noted by the historian, Yaqt (d. 1229), who describes their visibility from miles away serving as a beacon for travelers (Wilber, 1939, p. 23, n.25). A noteworthy early example of the use of glazing to highlight a particular pattern is the mid-twelfth-century tympanum of the Gonbad-e Sorkh at Maragha (Fig. 8). Its arcuate shape encloses three networks of intersecting hexagons, dodecagons, and nonagons sharing the same center point, with nonagons

highlighted in turquoise glaze (Bier, 2012). The composition clearly reflects extraordinary mathematical understanding of how polygons and

polygonal networks relate to one another geometrically. Surrounding the geometric composition, an elegant historical inscription gives the building's date of construction as 4 March 1148 CE and the name of the patron, Fakhr al-Din Abu 'l-'Izz 'Abd al-'Aziz ibn Mahmud, a local ruler also known as Qawam-e Azarbayjan, who 15 years later was host to a famous Jewish mathematician, Abu Nasr Samaw'al b. Yahya al-Maghribi, born in Baghdad (his father was from Spain). Samaw'al retired to Maragha and converted to Islam on Friday, 8 November 1163, as he reports in his autobiography, which was completed in 1167 (Schmidtke, 2013).

From the late twelfth century until the Mongol conquests of the thirteenth century, brick monuments in Iran, Iraq, and Azerbaijan demonstrate an aesthetic predilection for patterns with intersecting polygons, including stars (Pope & Ackerman, 1938/1939). The earlier use of intersecting squares, octagons, hexagons, and dodecagons, as at Kharraqan in Iran (Stronach & Young, 1966) in the late eleventh century and at Chist-e Sharif in Afghanistan (Broug, 2013, Fig. 1.1), of the late twelfth century, is superseded by patterns in which the arms of star polygons are extended to create "petals," and lines are further extended to meet edge extensions of other star polygons by means of point joining. In several instances, such techniques are carried to an

G

extreme: the decagonal prismatic mausoleum commissioned by Mo'mine Khatun at Nakhchivan in cut brick (Fig. 9) shows evidence of 11- and 13-gons (dated 1186), and a pattern executed in cut brick on the Choli Minaret at Erbil dating from the late twelfth century (Fig. 10) shows a pattern with 11- and 14-gons as reconstructed (Ajlouni & Justa, 2011). In the citadel at Aleppo, a pattern carved in wood from an Ayyubid panel in the early thirteenth century shows a progression of rayed polygons forming a sequence from 12-, 11-, 10-, 11-, and 12-gons, as analyzed by Herzfeld (1943), which is noted and discussed more recently by several authors (Allen, 1988, p. 53 and Fig. 57; Tabbaa, 2001, p. 96, Fig. 45). Bonner (2015) notes the presence of a more elegant rendition of the same pattern on the portal of a Seljuk monument in Anatolia, the Erkilet Kiosk in Kayseri (dated 1241). The design appears in Schneider (1980, no. 417). Such complex patterns, with or without illusionary interlacing, suggest an extensive array of experimentation with geometric shapes in polygonal networks and an ongoing effort to achieve more elegant refinement.

***Girih*: Grid-Based Patterns**

In the scholarly literature, the term *girih* (Persian, “knot”) has been applied to this ornamental tradition although its first documented appearance is attributed to architects working in nineteenth-century Central Asia (Baklanov, 1947). Necipoğlu (1995) carefully recounts the historical use of this term and consciously applies it to describe an artistic mode that is expressed through diagrams in the Topkapi scroll, which is an undated, anonymous scroll without text. By means of comparative stylistic and contextual analysis, Necipoğlu (1995, p. ix) ascribes this seminal historical document to the Timurid-Turkmen realm of Iran in the late fifteenth-early sixteenth century, but accepts that it is indicative of a much longer developmental evolution of designs used for architectural ornamentation. Other authors use the term *girih* with slightly different inflections (Denny, 2002; Rogers, 1973; Tabbaa, 2001). The Topkapi scroll, published in a 2:1 facsimile edition (Necipoğlu, 1995), serves as a primary source, the data from which has been utilized in numerous

Geometry in Islamic Art, Fig. 10 Erbil, Iraq. Minaret Choli, panel of cut brick and turquoise glaze with 11-gons and 14-gons. Pattern reconstruction, as a sequential process as developed by Ajlouni and Justa (2011, Fig. 4)

contemporary studies in recent years to understand mathematical aspects of pattern construction in two and three dimensions, knowledge of which had been lost. Lu and Steinhardt (2007a) introduced the term “*girih* tiles” for what Bonner (2003) had termed sub-grids that may have allowed for the possibility of modular constructions (see also Sarhangi, Jablan, & Sazdanovic, 2005; Sarhangi, 2008a). The Topkapi scroll illustrates several design templates that demonstrate such sub-grids (see Cromwell, 2010c), in which one-point or two-point matching rules apply. Bonner (2003) associates these patterns with the design methodology he calls the “polygonal technique,” which is similar to the “polygons in contact” identified by Hankin (1925), taken up by Kaplan (2000a, 2000b, 2004, 2005) in relation to the use of computer technologies to generate Islamic star patterns.

In *Encyclopedia Iranica*, the entry for *gereh-sāzi* defines the term as “making knot” and treats it in relation to woodwork (Blair, 2012) and architecture (Milwright, 2012). The section on woodwork focuses on the early fourteenth

century in Iran, but omits reference to its important Zengid and Ayyubid antecedents, which reflect the acknowledged skill of three generations of woodworkers from Aleppo named al-Ma’ali, whose names are inscribed in their works (Mayer, 1958, pp. 48, 63, 65; Tabbaa, 2001, pp. 91, 94, 96). The value accorded such works is affirmed by historical circumstances: the task of installing the famous minbar (Fig. 11) commissioned by Nur al-Din al-Zanji (1146–1174) in the Aqsa Mosque in Jerusalem when the city was restored to Muslim rule after the Crusades fell to his successor, Saladin (Singer, 2008). And the Damascus-born thirteenth century biographer, Ibn Abi Usaibi’a, mentions a carpenter given the title *muhandis* (Arabic: architect or engineer), who had studied geometry with the greatest mathematician of his age, Sharaf al-Dīn al-Ṭūsī (c.1135–1213 CE) (Tabbaa, 2001, p. 88; Mayer, 1958, p.53).

Blair (2012) describes the product of the *gereh-sāzi* technique as geometric interlaced strapwork ornament within a lattice framework and notes that it became “very popular in the

Geometry in Islamic Art, Fig. 11 Jerusalem. Al-Aqsa mosque, minbar (destroyed by arson in 1969). Detail. Carved and inlaid wood, made in Aleppo, late twelfth century. (Photo by K. A. C. Safavid period.” From the Safavid period onward, colored glass windows, *orosi*, follow similar layouts of geometric patterning (Koliji, 2012b). And the design scrolls of the Qajar state architect, Mirza Akbar, now in the Victoria and Albert Museum, London, attest to a continuation of the tradition into the late nineteenth century (Wade, 2015 <http://patterninislamicart.com/drawings-diagrams-analyses/7/mirza-akbar-architectural-scrolls>).

Periodic and Quasiperiodic Patterns

Contemporary crystallographic interest in quasicrystals and the mathematical study of

quasiperiodic patterns have drawn recent attention to historic two-dimensional designs present in Islamic architecture from late twelfth century Iran (Bonner, 2003; Castéra, 2011; Lu & Steinhardt, 2007a, 2007b; Makovicky, 1992, 2007, 2008), with quasiperiodic octagonal lattices and decagonal patterns also recognized in Spain and Morocco (Makovicky & Fenoll Hach-Alí, 1996; Makovicky, Pérez, & Fenoll Hach-Alí, 1998). Castera (2003) considers self-similarity in *zellij* work in Andalusia and Morocco, and muqarnas, offering information concerning both transformation rules and the recursive process in two and three dimensions; the examples he considers have fourfold symmetry. Debate continues concerning the presence of periodicity – in which translational symmetry is key – in contrast to the long-range global order of quasiperiodic patterns, in which there is a high degree of symmetry without translation (Al Ajlouni, 2012; Bier, 2013; Cromwell, 2009; Saltzman, 2008) (Figs. 12, 13 and 14).

Lu and Steinhardt (2007a) focus on one early antecedent of the quasiperiodicity of patterns being studied today, which are at the forefront of mathematical thinking and identifying its underlying tiling. This pattern, which surrounds the shaft of the decagonal Gunbad-e Kabud in Maragha, had earlier been studied in detail by Makovicky (1992), a crystallographer (see also Makovicky, 2007, 2008 and Bier, 2011). As mentioned above, Bonner (2015) emphasizes that four varieties of pattern families (Fig. 13) may be produced based on the angles of intersecting lines (acute, median, obtuse, and two-point). He also notes that the underlying polygonal structures found in the fivefold system (especially the “ring of pentagons” that typically surround the decagons) very likely informed artists in their composition of more complex underlying generative tilings for patterns with multiple centers of localized symmetry. Based on this interpretation of design methodologies, Bonner (2015) argues that Lu and Steinhardt’s girih tiles (2007a) comprise a limited subset of the larger set of fivefold modules of the Islamic ornamental tradition, namely, only the median pattern family in which 72-degree angles are paramount.

generation by Rima Ajlouni (2012, Fig. 7), showing long-range quasi-periodic pattern with local five-fold and global ten-fold radial symmetries

From the height of the Ottoman Empire in the sixteenth century, two carved and pierced medallions framing the marble *minbar*, or pulpit, of the Şehzade Mosque in Istanbul (Fig. 14) and the Selimiye Mosque in Edirne (both monuments designed by the great Ottoman imperial architect Sinan) also show quasiperiodic patterns (Bier, 2014). Other pierced openwork reticulated marble screens show periodic patterns of intersecting polygonal networks, demonstrating a systematic study of polygonal nets at least 50 years before publication of Kepler's *Harmonices Mundi* in 1619 (Bier, 2014). From the *Risale-ye Mi'mariyya*, a seventeenth century treatise on Mehmed Agha, a chief imperial architect trained by Sinan, we know that architects were trained in mother-of-pearl work (Fig. 15) in the imperial gardens of Topkapi Palace, as a means of learning

the “science of geometry,” which was considered the basis of architectural knowledge (Crane, 1987).

Handasa/Muhandis

The term *handasa* (Arabic: geometry) is a loan word from Middle Persian, its use dating from before the Arab conquests of the seventh century (Suter, 2014). *‘Ilm al-handasa* is both “knowledge of geometry” and “the science of geometry,” a genitive-possessive construction. The title *muhandis* reflects an Arabic grammatical construction applied to the Persian loan word as if it were an Arabic verb with a quadriliteral root. Although it came to mean architect or engineer, its original primary meaning would have been

Geometry in Islamic Art, Fig. 13 A polygonal network (for example, with decagons and a ring of pentagons as illustrated) serves as a sub-grid to yield four pattern

families based upon angles of intersection at mid-points (acute, obtuse, median) or two-points. Analysis developed by Jay Bonner (2003)

associated with agency, as “geometrician” or “one who works with geometry.”

In the thirteenth century, a historian of the Delhi Sultanate, Juzjani, extols the palatial architecture of the Ghurids in his hometown of Firuzkuh as being what “no geometrician has made manifest.” Discounting fulsome panegyric, it seems reasonable to assume that this reflects the actual practice of builders and craftsmen – making geometry manifest.

Geometry as Cultural Expression (Geometry Made Manifest)

That geometry itself was held in high cultural esteem is clear from the role it plays in various script styles, both related to calligraphy of the Qurʾān which Muslims accept as having been revealed in Arabic and in the chancery (Blair, 1992, 1998, p. 206; Schimmel, 1984), as well as calligraphic inscriptions on architectural monuments. A particular focus appears in the early

calligraphic reforms of Ibn Muqla (d. 940) (Tabbaa, 1991, 1994, 2001), and the spread of Arabic scripts to other languages must also be noted. Geometry is also referenced in Arabic and Persian poetry (e.g., ‘Unsuri, Sana’i) and in the late twelfth century, Nezami (Soucek, 1975); it also figures in poetic descriptions of palace architecture (Meisami, 2001). A theological dimension may also be inferred; when Sana’i (d. 1131–41), for example, was poet laureate of the Ghaznavid court, he likened “the ability to behold the divine manifestation. . . to the intellectual way of perception of a geometrician” – “You only see with your imagination and your senses when you have not learned about lines, planes, and points” (De Bruijn, 1983, p. 238).

Points, lines, and angles, yielding intersecting lines and patterns in the plane, occur with such frequency in the pre-Mongol monuments of Afghanistan, Iran, Azerbaijan, and Iraq, as to suggest that they concern a visual discourse related to mathematical ideas. The dynamic play with patterns in the plane in the eleventh and twelfth centuries parallels the design innovations in three-dimensional forms including varieties of prismatic structures for tomb monuments, conical and pyramidal roofing arrangements, and the early development of *muqarnas* (Ashkan & Ahmad, 2012; Bloom, 1988; Tabbaa, 1985).

Scholarship on geometry in Islamic art and architecture in the twentieth century has often reflected Western prejudices, including notions that geometric patterns are abstract, repetitive, and nonrepresentational and therefore bear no meaning. Framing the interpretation of ornament as ornamental and decorative is a discourse based in the academic disciplines of the histories of art and architecture, which may have precluded cultural understanding of geometric patterns within their original cultural contexts. One renewed effort to define aesthetics in Islamic art relates optical illusion and aesthetic metaphor and explores decorative patterns of the Alhambra in terms of phenomenology and semiotics (Gonzalez, 2001). Another compares artistry to nature and identifies “reality [to be] less impressive than its artistic image,” as the “quintessence

of the Islamic visual arts” (Behrens-Abouseif, 1999, p. 141), drawing upon the works of al-Farabi, Ibn al-Haytham, and Ibn Sīnā. Belting (2011) also draws upon the theories of vision of Ibn al-Haytham, linking Arabic science to the development of linear perspective and Renaissance art. If Islamic geometric ornament is reexamined within the particular cultural context of its creative formative period in the eleventh and twelfth centuries, it may well be found that it is an expressive rather than symbolic artistic form and may be reinterpreted in relation to other forms of cultural expression – including Qur’ānic inscriptions and *tafsir* (Arabic exegesis or commentary), poetry, and contemporary texts on mathematics. In approaching geometry in Islamic art in this relational manner, we may be able to chart a new course for the study of pattern as lines of mathematical thought expressed visually.

- al-ḥisāb* (Key of Arithmetic) of Jamshīd al-Kāshī (d. ca. 1430), in the astronomical *al-Qānūn al-Mas'ūdī* (Masudic Canon) of Abū'l Rayḥān al-Bīrūnī (973–1048) and in his treatises on astrolabes, as well as in the encyclopedic *Kitāb al-shifā* (Book of Healing) of Abū 'Alī ibn Sīnā (Avicenna 980–1037). There are also special geometric treatises, commentaries on Euclid, and treatises on geometrical theorems, calculations, constructions, and the foundations of geometry.
- Calculations of areas of plane figures and of volumes of solids were considered in the chapter “On mensuration” of the algebraic treatise of al-Khwārizmī. Many rules in this entry coincide with the rules of Hero's *Metrics* (first century AD) and of Indian mathematicians of the fifth and sixth centuries. For the area S of a circle with radius r , he applies the rule $S = \pi r^2$, where $\pi = 3\frac{1}{7}$, $\sqrt{10}$, 62832/20000.
- The contents of this entry are similar to the Hebrew *Mishnat ha-middot* (Treatise on Measuring), which was believed to be part of the *Talmud* written in the second century AD. Recently Zarfatti (1968) showed that this book was written after al-Khwārizmī's treatise and under its influence.
- Many treatises on geometric calculation were written by Thābit ibn Qurra. In his *Kitāb fī misāḥa al-ashkāl al-musaṭṭaḥa wa 'l-mujassama* (Book on Mensuration of Plane and Solid Figures), he provides many rules for measuring area and volume. For example, there is his general rule for the calculation of the volume V of a right round cylinder, cone, and truncated cone expressed by one formula: $V = \frac{1}{3}h(S_1 + S_2 + \sqrt{S_1S_2})$.
- In his *Kitāb fī misāḥa qaṭ' al-makhrūṭ alladhī yusammā al-mukāfī* (Book on Mensuration of a Conic Section Named Parabola) and other works, Thābit tackles many geometric problems. Among these are the problems of calculating the area of a segment of a parabola, the volume of segments of solids obtained by the revolution of segments of a parabola, and of the area of a surface of an oblique round cylinder. Thābit calculated the area of segments of an ellipse by means of an

Geometry in Islamic Mathematics

Boris A. Rosenfeld
PA, USA

Many original Muslim geometric works are “books” or chapters of great mathematical, astronomical, and encyclopedic works. Geometrical parts are contained in the algebraic treatise of al-Khwārizmī (ca. 780–850), in the *Miftāḥ*

equi-affine transformation of the ellipse onto a circle with equal area. His grandson Ibrāhīm ibn Sinān, (908–946) in his *Kitāb fī misāḥa al-qaṭʿ al-mukāfī* (Book on Mensuration of a Parabola) calculated the area of a segment of a parabola by means of a general affine transformation. Wayjan al-Qūhī (tenth to eleventh centuries) and Ibn al-Haytham (965–ca. 1040) calculated the volumes of segments of solids obtained by the revolution of segments of parabolas that Thābit had not considered.

Al-Bīrūnī, in the mathematical part of his *Masudic Canon*, calculated the sides of a regular triangle, square, pentagon, hexagon, octagon, and decagon inscribed in a given circle. Also, he provided the length $C = 2\pi r$ as the circumference of a circle where $\pi = 3.7305910$ in sexagesimal fractions and 1628631471/518400000 in decimal. Al-Kāshī in his *al-Risāla al-muḥīṭiyya* (Treatise on Circumference) calculated the length $C = 2\pi r$ by means of the calculation of the perimeter of regular inscribed and circumscribed polygons with 3.2^{28} sides. The number of sides was chosen on the condition that the difference between these perimeters for the great circle of the sphere of fixed stars must be less than the “width of a horse hair.” The result was expressed in sexagesimal and decimal fractions as 3.829440472553725 and 3.14159265358979325. In the last case, the calculation is correct up to 17 digits.

The teachers of Thābit ibn Qurra, the brothers Muḥammad (d. 872), Aḥmad, and al-ḥasan Banū Mūsā ibn Shākir, in their *Kitāb al-shakl al-mudawwar al-mustaṭīl* (Book on an Oblong Round Figure), proposed the construction of an ellipse by means of a string attached to its foci (the so-called “Gardiner’s construction”). Thābit himself solved two classical problems of antiquity: the construction of two mean proportional magnitudes between two given ones ($a : x : y : b$), which is the Delic problem of the duplication of a cube (if $b = 2a$) and the trisection of an angle. He also proposed the spatial construction of a semiregular polyhedron with 14 faces, which some now say was discovered by Archimedes.

The great philosopher Abū Naṣr al-Fārābī (ca. 870–950) proposed many geometric

constructions of parabolas, regular polygons, squares equal to three given equal squares, constructions with one opening of the compass, and constructions on the sphere. These were also studied by Thābit’s pupil’s pupil Abū’l-Wafā al-Būzjāni (940–998) in the *Kitāb fī mā yakhtāju ilayhi al-ṣāniʿ min aʿmāl al-handasiyya* (Book on What is Necessary from Geometric Construction for the Artisan).

Ibrāhīm ibn Sinān ibn Thābit proposed many ways to construct a parabola (including al-Fārābī’s one), ellipse, and hyperbola. One of the constructions of an ellipse is based on the compression of a circle; one of a hyperbola is based on a projective transformation of a circle.

Al-Qūhī described the instrument for the construction of conics, which he invented. It is a compass in which one leg varies in length and the second leg can change the angle of its slope to the plane. Many methods for the construction of conics were described by al-Bīrūnī in *Istīʿāb al-wujūh mumkina fī ṣanʿa al-aṣṭurlāb* (The Exhaustion of Possible Ways of Constructing an Astrolabe). In particular, he mentions the “Gardiner’s construction” of Banū Mūsā, the perfect compass of al-Qūhī, and constructions of all three kinds of conics based on projective transformations.

Al-Fārābī revised the order of the first definitions of Euclid. The first definition of Book 1 of the *Elements* was that of a point as “that which has no parts.” Later, Euclid defined a line as “a breadthless length” and a surface as “that which has length and breadth only.” In Book 11, he defined a solid as “that which has length, breadth, and depth.” Al-Fārābī, following Aristotle, defined a solid as the first abstraction from a physical body, a surface as the abstraction from a thin solid, a line as the abstraction from a narrow surface, and a point as the abstraction from a short line. The same order of geometric definitions was used by al-Bīrūnī in the geometric part of his *Kitāb al-taḥfīm li-awāʾil ṣināʿa al-tanjīm* (Book of Instruction in the Elements of the Art of Astrology).

In his *Taḥrīr Uqlīdis* (Exposition of Euclid), Naṣīr al-Dīn al-Ṭūsī added to Euclid’s axioms that of the existence of points, lines, and surfaces,

and the axiom of possibility of choice of a point on an arbitrary line and surface and of a line on an arbitrary surface and through an arbitrary point. There are also analogous axioms ascribed to al-Ṭūsī's version of the exposition of Euclid's *Elements* and in the geometric part of the encyclopedic work of his pupil Quṭb al-Dīn al-Shīrāzī (1236–1311). In both these works, there are also attempts to prove Euclid's first three postulates about the ideal ruler and compass.

In al-Shīrāzī's commentaries to al-Ṭūsī, the rules of the theory of syllogisms from Aristotle's *Analytics* are systematically used.

In many Islamic treatises, the problem of mathematical atomism was discussed. Aristotle's ideas, on which Euclid's *Elements* is based, ousted the mathematical atomism of Pythagoras and Democritus. According to them, finite solids, surfaces, and lines consist of a finite number of "atoms." Pythagoras said these atoms were points without sizes, and the sizes of finite figures were created by the distances between them. According to Democritus these atoms were particles with very small but finite sizes. In medieval Islam, the ideas of mathematical atomism were held by Muslim scholastics, the *mu' tazila* and *mutakallimūn*, who wanted to find a rational explanation for Islam. They believed that time consists of a separate "now" and explained by means of this view that God creates the world anew every instant. Among the *mu' tazila*, there were adherents of both types of mathematical atomism. The first school was headed by Abū'l-Qāsim al-Ka' bī (d. 932) whose nickname al-Ka' bī means "cubical"; the second was headed by Abū'l-hāshim al-Jubbā' ī (820–933). Democritus' ideas were also held by the philosopher and alchemist Abū Bakr al-Rāzī (865–952). The idea of mathematical atomism was also mentioned by al-Shīrāzī in his commentaries on a treatise by al-Ṭūsī.

Islamic mathematicians often attempted to prove Euclid's fifth postulate on which the theory of parallel lines in his *Elements* is based. This postulate is much more complicated than the first four. It asserts that, if a straight line falling on two straight lines makes the interior angles on the same side together less than two right angles, the two straight lines, if produced indefinitely,

meet on that side in which the angles together are less than two right angles. Attempts to prove this axiom as a theorem were made by Archimedes (third century BCE), Posidonius (second to first centuries BCE), Ptolemy (second century AD), Proclus (fifth century), and Simplicius (sixth century). In their proofs, there was the logical error of *petitio principii*, i.e., the implicit use of an assertion equivalent to the one being proved.

The first Islamic mathematician who attempted to prove the fifth postulate was al-'Abbās al-Jawharī (first half of the ninth century). In his *Iṣlāḥ li-kitāb al-Uṣūl* (Improvement of the Book "Elements") he proposed a proof based on the assertion that a straight line intersecting both sides of an angle can always be drawn through any point inside this angle.

Thābit ibn Qurra made two attempts to prove the fifth postulate. His two treatises on parallel lines were written in Syriac and then translated by him into Arabic. The first proof is based on the assertion of the existence of "a simple motion"; i.e., a parallel translation equivalent to the existence of equidistant straight lines and to the existence of a rectangle. The second proof is based on the assertion that, if two straight lines diverge on one side of a line falling on them, they necessarily converge on the other side. From this follows the existence of a parallelogram. An analogous error was made by al-Faḍl al-Nayrīzī (d. 922) in his *Risāla fī bayān al-muṣāḍara al-mashhūra min Uqlīdis* (Treatise on the Proof of the Known Postulate of Euclid).

Ibn al-Haytham also made two attempts to prove the fifth postulate. One attempt was based on the same error as in Thābit's first treatise. In this proof, Ibn al-Haytham first considered quadrangles with three right angles ("the Lambert quadrangles") and three hypotheses about their fourth angle. The hypotheses of acute and obtuse angles were refuted by means of the existence of a rectangle. The second attempt was written in his last years. Here was the first proof of the fifth postulate which was free from logical error. At first the postulate was replaced by another more evident one and was proved by means of it. This new postulate was: two intersecting straight lines

cannot be parallel to a third line. This postulate in the form “if the point A and a straight line a are given, it is impossible to draw more than one not intersecting line through A in their plane.” This is now known as “the Playfair postulate” or “the strong Hilbert axiom of parallels,” after Europeans who later came up with the same axiom.

Also free from logical error was ‘Umar al-Khayyām’s proof of the fifth postulate in his *Sharḥ mā ashkala min muṣādarāt kitāb Uqlīdis* (Commentaries on Difficulties in Introductions of Euclid’s Book). In this work, Khayyām proved the postulate on the basis of a postulate which he called the “fourth principle of the philosopher (Aristotle).” “Two converging lines intersect and it is impossible for them to converge in the direction of divergence.” In this proof, he first considered equilateral quadrangles with two right angles at their low bases (which we now call “the Saccheri quadrangles”) and three hypotheses about their equal upper angles. The hypotheses of acute and obtuse angles are refuted by means of this fourth principle. These two hypotheses, which are analogous to those of Ibn al-Haytham (his quadrangles are halves of Khayyām’s), are fulfilled in hyperbolic and elliptic non-Euclidean geometries, respectively. Ibn al-Haytham and Khayyām actually proved some theorems of these geometries first.

Naṣīr al-Dīn al-Ṭūsī considered the theory of parallel lines. In the treatise, al-Ṭūsī explained the proofs of al-Jawharī, Ibn al-Haytham (only the second), and Khayyām (not completely) and considered the same quadrangles and the same three hypotheses as Khayyām. However, he made the same logical error *petitio principii*. In the book, written after the critical letters of Qayṣar al-Hanafī (ca. 1170–1251), he explained the same proof, but before it he formulated the postulate similar to Khayyām’s, and thus does not make a logical error.

Al-Shīrāzī also made an attempt to prove the fifth postulate based on a logical error: he supposed that the distance between lines which do not intersect is constant.

We saw that in the proofs of the fifth postulate by Thābit ibn Qurra and Ibn al-Haytham “a

simple motion” was used. The application of motion to geometry was used by Pythagoreans who considered lines as traces of moving points and surfaces as traces of moving lines. However, this application was rejected by Aristotle, who considered geometric solids as abstractions from physical bodies, surfaces as abstractions from thin solids, lines as abstractions from narrow surfaces, and points as abstractions from short lines. Following Aristotle, Euclid tried in his *Elements* to avoid the application of motion. Khayyām criticized the application of motion by Ibn al-Haytham.

We also saw that Thābit ibn Qurra and his grandson Ibrāhīm ibn Sinān used affine transformations in their geometric treatises, and al-Bīrūnī also used projective transformations.

An astronomical instrument called an astrolabe was very popular in the Middle Ages. It was based on the projection of the celestial sphere onto its plane. Many treatises on the construction of astrolabes contain descriptions of different projections. In the *Kitāb ṣan‘a al-aṣṭurlāb* (Book of the Construction of the Astrolabe), Aḥmad al-Farghānī (d. 861) described the stereographic projection. That and others were described by al-Bīrūnī in his *Exhaustive Ways of Constructing an Astrolabe*. Al-Bīrūnī applied a stereographic projection for determining the azimuth of *qibla* (the direction to Mecca). He also used the stereographic and some other projections of a sphere on to a plane in his *Risāla fī taṣṭīḥ al-ṣuwar wa tabṭīḥ al-kuwar* (Treatise on the Projection of Designs on to a Plane and on the Map of Spheres on a Plane), which was devoted to problems of cartography.

In the *Elements*, Euclid used the plane geometrical algebra inherited from the Pythagoreans. In this, he represents the products $a \times b$ as rectangles with sides a and b and provides a geometric representation of algebraic equalities. For instance, there is a representation of the formula $(a + b)^2 = a^2 + 2ab + b^2$ by decomposing the square $(a + b)^2$ on two squares a^2 and b^2 and two rectangles $a \times b$. In Archimedes’ *Lemmas* there is an analogous decomposition of a circle with diameter $a + b$ on two circles

with diameters a and b and two “arbelons.” Analogous representations of the formula $(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$ by decompositions of the cube $(a + b)^3$ and of the sphere with diameter $a + b$ were proposed by Abū Saʿīd al-Sijzī (ca. 950–1025).

Apparently, the idea of “geometric” names for powers, square-square for x^4 , square-cube for x^5 , cube-cube for x^6 , and so on, was borrowed from Diophantus’ *Arithmetics*.

Islamic mathematicians used rectangular and oblique coordinates connected with conics: the axes of these coordinates were one of the diameters of a conic and the tangent line at one of its ends. Each point of a conic was determined by half of its chord conjugate with this diameter from a given point to the diameter and by the segment of this diameter from its end (vertex) to the meeting point of the chord with the diameter. They called these coordinates “ordered lines” and “line cut from the vertex,” respectively. (Our terms “ordinate” and “abscissa” came from Latin translations of these expressions.) These coordinates were used by Khayyām in his *Risāla fī l-barāhīn ‘alā masā’il al-jabr wa’ l-muqābala* (Treatise on Demonstrations of Problems of Algebra), which was devoted to the solution of cubic equations by means of the intersection of conics.

Islamic astronomers and geographers following Ptolemy used the geographical coordinates longitude and latitude for the surface of the Earth, and analogous ecliptical coordinates with the same names, the horizontal coordinates azimuth and altitude, and the equatorial coordinates right ascension (or horary angle) and declination for the celestial sphere. Thābit ibn Qurra determined the positions of the ends of the shadows of the gnomon on the plane of a plane sundial by rectangular coordinates which he called, by analogy with the geographical coordinates, longitude and latitude, and by polar coordinates which he called azimuth and length of shadow.

Muḥammad al-Khwārizmī in his geographical treatise *Kitāb ṣūra al-arḍ* (Book of the Picture of the Earth) proposed the classification of curved lines and used the names of different kinds of

lines in his descriptions of rivers, seacoasts, and islands between points with given geographical coordinates.

In addition to their original contributions, Muslims made many translations of Greek works. In many cases, the Arabic version of the work is the only one extant today. The most important Greek geometric work, Euclid’s *Elements*, was translated into Arabic in the ninth century AD by al-Ḥajjāj ibn Yūsuf ibn Maṭar and Iṣḥāq ibn Ḥunayn al-ʿIbādī. The last translation was edited and supplemented by Thābit ibn Qurra (836–901), who was also the translator of other works of Euclid, of many works of Archimedes, of the *Conics* of Apollonius, and of many Greek mathematical works. These, together with a geometric treatise of his teachers the brethren Banū Mūsā and his *Kitāb al-mafrūdāt* (Book of Assumptions) constituted the so-called “middle books” which were studied between Euclid’s *Elements* and Ptolemy’s *Almagest*. Later, many Muslim revisions of other Greek mathematical works appeared.

Geometry in Japanese Mathematics

Yoshimasa Michiwaki

Western mathematics is concerned very much with logic based on proof and demonstration. Japanese mathematics in the Edo period (1603–1867), which is called *Wasan*, has its origin in China, and from the beginning put its emphasis on application, mainly on application in daily life. At the beginning of *Wasan*, experts studied practical aspects of mathematics, such as deriving the areas of figures and the volumes of solid bodies. However, in the developing period, they began to devise questions which provided conclusions based on the beauty of figures and complicated calculation. They especially liked questions on geometrical figures, and they had their own ways of studying. When they studied circles, they tried to increase their number, change their positions, and consider them as ellipses. They also tried to expand into three dimensions. Because of the national isolation policy of Japan, *Wasan* experts were kept in guild-like groups. The study of *Wasan* became

very complicated; practitioners could not concentrate on the main themes but had to act as if their studies were rather like a hobby.

Wasan was formulated in the latter half of the seventeenth century by a Japanese mathematician, Takakazu Seki (or Kowa Seki) with the text *Jinko-ki* as its basis. The interest of *Wasan* experts in those days was to solve the questions left unsolved in *Jinko-ki* and other mathematical texts: that is, to calculate the areas and volumes of planes and solid figures, and also the length of chords and arcs and the area surrounded by them. Takakazu Seki, before he succeeded in systematizing *Wasan*, tried hard to solve those questions, and in the process studied parabolas, hyperbolas, and also the spirals of Archimedes. And he partially succeeded in measuring ellipses.

In the field of algebra, Seki used a determinant of five dimensions in his work *Kaifukudai-no-ho* published in 1683. In the area of geometry, he derived a relative equation between a side of a regular polygon and radii of an inscribed circle and a circumscribed circle. This arose from a theory on regular polygons. He also made great accomplishments in the field of *Enri*: this word may be translated as “circle principle” or “circle theory”, being derived from the fact that the measurement of the circle is the first subject that it treats. He repeated doubling the numbers of the side of an inscribed, regular polygon, and achieved the correct number for π . He devised a calculation method for circles – integral calculation – studying the relation among the chord, the arrow, and the arc. He also worked in other fields, such as the calendar.

After the publication of such works as *Seiyo Sampō*, *Shinpeki Sampō*, *Sampō Kokon Tsuran*, and *Sampō Tensei-ho Shinan*, interest in *Wasan* was very much aroused. For example, *Sangaku* (Mathematical Tablets) were dedicated to shrines and Buddhist temples. Some of these are beautiful, with figures of red, blue, and yellow. The definitions of the figures are not written on the tablets, but the drawn figures (questions) themselves illustrate the things necessary to solve the questions. These questions posed by *Wasan* experts are combined questions, such as a square and a square, a straight line and a circle, a circle

and plural circles (or ellipses). There are questions on the length of a square side, a straight line, and the radius of a circle. There are also questions on the number and areas of circles put into one circle. These questions are expanded from “plane” to “solid” and from “limited” to “unlimited.”

Wasan experts tried to derive the theorems to solve questions, and in the process they reached general laws by something like an inductive method. They sought a general equation with some sort of inspiration. One of these *Wasan* experts, Nushizumi Yamaji, stated in his *Sampo Ruiju* (Vol. 3) the same ideas as in Descartes’ circle theorem but in a different way. A theorem like Descartes’ was introduced in the mathematical texts of the first half of the nineteenth century, such as *Kokon Sankan* by Gokan Uchida.

Wasan in the Bunka and Bunsei period (1804–1818–1829) was at its peak. In *Suri Mujinzo* by Nagatada Shi-raishi, one finds a technique or theorem called *Bosha Jutsu*, which has exactly the same idea as Casey’s. This theorem is considered an extension of Ptolemy’s.

Shingen Takeda wrote *Shingen Sampō*. In the first volume of this work, there is a problem called Clever Ways to Cross the Twenty-Eight Bridges in Naniwa (now Osaka).

Another *Wasan* expert, Zen Hodoji, learned many things through visiting various districts and teaching students in each district. In one of his works, *Kan-shinko Sanhen*, there are questions which are close to the present “inversion” formula. We are not sure how he reached the inversion formula, but the result was correct.

As was stated before, *Wasan* experts were inspired to find a solving technique. *Kyokkei Jutsu* and *Henkei Jutsu* should be introduced here. *Kyokkei Jutsu* is explained in *Sampo Kyokkei Shinan* written by Hiroshi Hasegawa and his student, Giichi Akita. Special figures – *Kyokkei* – are used in this method. Beside this, Hasegawa wrote *Sampo Henkei Shinan* with his student, Teishin Heinouchi. In this, you find a sentence which says that “Questions with reasonable conditions, that is, questions with conditions enough to solve them are called “complete questions” while others with too

many or too few conditions are called “incomplete questions.” Some of these questions can be solved with insufficient conditions, and they are called *Kyoku Dai* (special questions). This book deals mainly with variations of *Kyoku Dai*. Both *Kyokkei Jutsu* and *Henkei Jutsu* deal with figures in special cases instead of general figures, but each technique is different. *Kyokkei Jutsu* has a tendency to make a mistake by trying to get an answer; *Henkei Jutsu* has no such tendency, but you find it difficult to get a *Kyoku Dai*. Each method is unique as a method of geometrical studies.

In the Meiji period (1868–1911), the new education system established in 1872 eliminated *Wasan* studies from public education, and adopted western mathematics.

However, in the Taisho and Showa periods (1912–1928–1988) mathematical leaders such as Tsuruichi Hayashi and Matsusaburo Fujiwara collected materials and wrote theses on various themes of *Wasan*, and its popularity was revived. The History of Science Society of Japan was established in 1941 and Kin-nosuke Ogura, counselor of the society, insisted that Japanese mathematics history be carefully considered. The Mathematics Club, later The History of Mathematics Society of Japan, was established in 1958 mainly to study *Wasan*. Seminar groups appeared in many districts, and magazines and theses were published. In 1979, the *History of Japanese Mathematics before the Meiji Period* (5 Vols.) edited by the Japan Academy was completed. All of the works mentioned in this essay can be found in this set.

Geometry in Mesopotamia and Egypt

Jens Høyrup

This article concentrates on the geometrical knowledge of the scribal traditions, not on what *could* have served for the construction of buildings. It must be observed that high technical precision is often achieved through the combination of quite elementary mathematics and sophisticated non-mathematical techniques. Anyone who has played with rulers and compasses knows that a regular pentagon can easily be made more precise through trial and error than by “exact” construction with all its accumulated errors. It is therefore next to impossible to

extrapolate from the high precision of for example prestige buildings to the particular kind of geometry used in their design, unless some kind of blueprint has survived. Even in such cases, when the tracing of a ground plan has subsisted or the building can be seen to be planned around base lines geared to the standard brick, all that may be concluded is often that *some kind of* geometrical knowledge is involved.

On the other hand, in Mesopotamia as well as Egypt, written texts with geometrical contents have survived, most of which are scribe school problems. Even when unambiguous (which is not always the case), they confront us with a problem of bias: scribal mathematics consisted in calculation; the texts always aim at the determination of a number (an area, a volume, the number of man-days needed to dig a ditch, etc.). Geometrical construction was not the concern of the scribes.

Mesopotamia

The sources for our knowledge of Mesopotamian geometry reach back to the later fourth millennium BCE. The earliest sources are not very informative, but they demonstrate that the length and area metrology, together with the basic techniques for area computation, go back to the first phase of writing. Sources from the third millennium become more copious, in particular towards its end. Sophisticated scribe school problems dealing with complex volumes only turn up in the Old Babylonian period (early second millennium) and disappear again from the horizon after 1600 BCE. Finally, some interesting texts have survived from the later half of the first millennium BCE.

Length metrology may have been created in the same process as writing and written administration. Already in the earliest written documents, area metrology is keyed to the length system – but some of its units appear to be old “natural” (irrigation, ploughing, or seed) measures which have been normalized so as to fit, while others have been created anew. These systems survive until the end of the Old Babylonian period. In the

late period, new quasi-natural measures (seed measures) allowing easier practical computation take over.

The basic volume measures coincide with the area measures, which are tacitly imagined as provided with the height 1 cubit. The system of hollow measures, on the other hand, is perplexingly complex, involving both traditional measures that have been normalized so as to fit the length system, and corrections introduced in order to facilitate practical computation of rations, cylindrical volumes, etc. A Mesopotamian specialty is the multiplicity of “brick measures”, using the terminology of volume measures but referring in fact to the number of bricks, for which several standard dimensions coexisted.

The Old Babylonian texts show us that square and rectangular areas as well as right triangles and trapezia were calculated as we would do it. No unambiguous standard term for the height of a triangle or a trapezium is present, and field plans show us that complex areas, including skew triangles and trapezia, were subdivided into “practically rectangular” quadrangles and “practically right” triangles. No concept of a quantified angle is present, the field plans seem simply to distinguish “right” from “wrong” angles.

In practical mensuration, working in an always slightly uneven terrain and not in an abstract Euclidean plane, what is laid out as a rectangle with traditional methods mostly turns out to have slightly different opposing sides. In this situation, the Mesopotamian scribes calculated the area according to the “surveyors’ formula”: average length times average width. The result always exceeds the true area, but not significantly if the angles of the quadrangle are approximately right. In school problems, where the formula served as a pretext for calculation, it was occasionally used in situations where the outcome was absurd. In practical field measurement, a single instance is known where the error is at least 100 %; whether this reflects general carelessness or the ignorance of a single scribe is not clear (it is even possible that a number written along a side is really meant to be the height, in which case there is no error in the computation but only a somewhat careless diagram).

Most often, the circular area was determined as $1/12$ of the square on the circumference (which is often the dimension most easily determined in practice by means of a piece of string). Translated into our idiom, this means that 4π was approximated as 12, or that $\pi = 3$. Other computations, such as the determination of the diameter from the circumference, agree with this; the Babylonians were thus aware that the circular area was the semi-product of the radius and the circumference.

Simple volumes (prisms, cylinders) were determined as the product of the base and the height – the formulation being that the base was “raised” to the height. Raising is a general term for multiplication based on considerations of proportionality – derived originally from volume determinations but in general use. The idea which underlies volume determination is indeed one of proportionality, since the base was understood as already provided with a standard height of 1 cubit. Similarly, a length could be understood as provided with a standard width of one length unit, and area computations (when not implicit in the construction of a rectangle) were hence also done by raising.

Complex volumes, such as truncated pyramids and cones, were determined by ad hoc methods, not always correctly or consistently. Several texts determine the volume of a truncated cone as that of a cylinder whose diameter is the average of the diameters of top and bottom. One of them determines the volume of a truncated square pyramid in the same way, but adds a correction term that makes the computation accurate (it is not quite sure whether the underlying reasoning is also correct). Other texts determine the volumes of truncated cones and pyramids by raising the average between top and bottom area to the height.

No later than the Old Babylonian period, the Pythagorean theorem was known and used for diagonal calculations. The purpose of a table text making use of Pythagorean triples is not fully decided, but it seems to be arithmetical rather than geometrical.

Already in the twenty-third century BCE, it was known that the square on the parallel transversal which bisects a trapezium is the half-sum

of the squares on the parallel sides. No text tells us how this formula was reached, but it follows without difficulty from consideration of two squares of which one is embedded concentrically in the other. Similar naïve-geometric reflections may have led to the discovery of the Pythagorean theorem; their presence is well attested in the so-called “algebra” texts.

A few texts testify to an interest in geometrical arrangements and in regular polygons; in the actual cases, however, the texts always calculate something (mostly an area). A text with a regular hexagon draws a height in one of the six isosceles triangles from which it is composed and computes its length and uses this in the determination of the area.

The few late Babylonian texts exhibit some changes in the area techniques, such as a more general use of heights in area determination.

Egypt

Third-millennium sources for Egyptian geometry are rare, and even though the precision of the great pyramids demonstrates both architectural and geometrical skill, they tell us little about the geometrical techniques that were in use.

The important mathematical texts – the *Rhind Mathematical Papyrus* and the *Moscow Papyrus* – date from the early second millennium BCE. Together with some minor texts and fragments and with what can be grasped from administrative documents, they present us with a coherent picture. In spite of some unsolved problems of interpretation and the presence of still open questions, nothing suggests that new sources might change our understanding of Egyptian mathematics radically. Nor does Egyptian technology, in spite of its indubitable sophistication, ask for *mathematical* knowledge beyond what we know from the papyri.

The evidence for the length and area metrologies of the third millennium is meager, but sufficient to show that they were intricate; the metrologies of the early second millennium derive from and expand a subset of the third-millennium systems.

In this “classical” period, the most widely used length unit was a “royal cubit” of seven palms. Also in use was a “short cubit” of six palms, together with units equal to the diagonal and semi-diagonal of a square with side equal to the royal cubit.

Area units were derived from the length units. The basic unit for land measurement was (100 cubit)²; for practical purposes, however, the Egyptians would often think in terms of strips with a standard breadth, as the Babylonians might also do.

Volume and capacity units were also keyed to the length system, but in a way that shows them to have originated independently – how else are we to explain that the basic volume unit was not 1 cubit³ but $\frac{2}{3}$ cubit³?

The areas of squares, rectangles and right triangles were calculated from length and width. The areas of trapezia and isosceles triangles were found as the product of height and average width, and the Rhind Mathematical Papyrus explains that this calculation of the triangular area means that the triangle is transformed into a rectangle. It should be noted that the height is a given or measured number, not the outcome of a computation.

The area of the circle was found as, $(\frac{8}{9}d)^2$ where d is the diameter. Translated into modern terms this means that the interesting constant was not π but, $\sqrt{\pi/4}$ which was approximated as 0.888... (where the true value is 0.8862...).

One problem (concerned with a “basket”) has been interpreted as the correct determination of the surface of a semi-sphere (equal to twice the cross section of the sphere). Another interpretation is that the text wants to determine the curved surface of a semi-cylinder, which will then also be correct, and would imply that the semi-circumference of the circle was found in agreement with the determination of the area.

Volumes of prisms and cylinders were found as the product of base and height (multiplied with a metrological conversion factor $\frac{3}{2}$). The *Moscow Papyrus* gives a correct determination of the truncated pyramid as $(a^2 + ab + b^2)(h/3)$ (where a and b are the sides of the upper and lower square and h the height).

Pyramid slopes were measured as horizontal recess, measured in palms, per cubit increased height. Most often, in texts as well as practice, the value is $5 \frac{1}{4}$, corresponding to a ratio 3:4 in pure numbers. Countless attempts have been made to demonstrate that the Cheops pyramid hides knowledge of either π or the Golden section (or both!) in its proportions. The proximity of certain ratios to these “mystical” numbers is, however, a mere consequence of the simple determination of the slope. Moreover, as we have seen, the Egyptians were not interested in the ratio π but in the equivalent number $\sqrt{\pi/4}$. There is no reason to believe that the pyramids testify to occult mathematical knowledge beyond the level revealed in the mathematical papyri. As Otto Neugebauer has pointed out, nothing is less secret than the “secret” knowledge of the Egyptians, the Greek magicians, the Gnostics, etc., all of whom have left an immense number of texts on occult topics, exceeding by far anything these cultures ever wrote on mathematics. Had the Egyptians possessed secret mathematical knowledge, we would certainly have been informed, as we are about the secret spells to be used in the Netherworld.

Even the oft-claimed Egyptian knowledge of the Pythagorean theorem (or at least of the fact that a 3-4-5-triangle is right) should be treated with circumspection. No single text suggests so. One of the arguments in favor of the assumption has been that this knowledge *might* have been used to construct right angles. This trivially correct observation made by Moritz Cantor has since then been quoted as information that they did so. The other is that the pyramid recess of 3:4 could have been chosen for this reason. As we have seen, however, the actual number used by the Egyptians was $5 \frac{1}{4}$; if the vertical distance was measured in cubits and the horizontal in palms, what was then to be done with the hypotenuse?

All of this concerned the mathematics of the scribes. Egypt, however, offers an exception to the rule that non-scribal geometrical techniques cannot be decoded. This exception regards not least the use of square grids, first of all in the pictorial arts but also in architectural planning.

In the pictorial arts the grids were connected to a so-called “canonical system” for the proportions of the human body. That is, whereas scribal geometry aimed at finding numbers from geometrical configurations, the artists determined geometrical configurations from numbers. Quarries and buildings also carry marks in large quantity that inform us about some of the measuring techniques that were used.

General Observations

Histories of mathematics tend to distinguish “exact” from “approximate” formulae. In so far as we are dealing with school traditions built on some kind of didactical argument, this distinction may be defended. Both Babylonian and Egyptian scribal training certainly involved argument, even though it was not deductive. However, when making this distinction we forget that formulae can only be exact with regard to ideal mathematical objects; when it comes to applying the formulae in real-life practice, *all* formulae become approximate.

Histories of mathematics – in particular general histories – also tend to translate into familiar terms. To a certain extent this is necessary, but it hides from view the fact that other cultures may use conceptualizations which are different from ours but just as good and consistent. Speaking of a Babylonian and an Egyptian “value for π ” suggests that the Babylonians, as we, looked for the ratio between the circumference and the diameter of a circle. However, to the Babylonians, the fundamental ratio was the ratio between the area of the circle and the area of the square on the circumference, and the terminology they used demonstrates that they really thought of this as a constructed geometrical square. The Egyptians, for their part, were interested in the ratio between the sides of the squared circle and that of the circumscribed square. Both conceptualizations are fully legitimate, also according to the gauge of mathematical theory, but they are certainly different from ours. If we neglect this, we only use the foreign culture as a mirror where we see – ourselves.

Later Developments

In the first millennium BCE, Egypt was conquered first by the Assyrians, then subdued by the Persian armies, and finally – after Alexander – ruled by a Greek dynasty. We cannot follow the phases of this in detail in the rare mathematical texts, but we observe that the Assyrian or Persian administrators and tax collectors brought some of their own methods to Egypt, such as, for instance, the “surveyors’ formula”. We also see that the practical geometries of the Babylonian and Egyptian cultures served as inspiration for the Greeks when they developed their theoretical geometry. But Greek theoretical development did not influence geometrical practice significantly, in spite of the real or affected efforts of certain Alexandrian mathematicians to educate the practitioners (in particular Hero). The ancient mathematical theoreticians were never sincerely interested in the problems encountered when geometry was to be practised – how to make sure that a ruler is straight, what to do if the compass opening is insufficiently large, how to prevent that the unavoidable imprecision in geometrical construction sums up to something unacceptable (in Euclid’s *Elements*, a circle is never drawn; it is presupposed to have been drawn by an anonymous “helping hand”, as pointed out by C. M. Taisbak). The synthesis between geometrical theory and geometrical practice was only achieved by the mathematicians of the Islamic Middle Ages, from ► [al-Khwārizmī](#) to al-Kāshī.

Ghulām Ḥusain Jaunpūrī

S. M. Razaullah Ansari

Aligarh Muslim University, Aligarh, UP, India

Biography

Abul Qāsim, alias Ghulām Ḥusain Karbalā’ī bin Fataḥ Muḥammad Jaunpūrī (1790–1862), was taught by his father and other contemporary mathematicians and astronomers. He was a court astronomer of the Rājah of Tikārī: Rāja Khān Bahādūr Khān Nuṣrat Jang, son of a Hindu Mahārāja Mitrajīt Singh and of a Muslim mother. Tikari is a town in South Bihar (24° 57 N, 84° 53 E), in India, where Ghulām Ḥusain carried out his astronomical observations, according to his own testimony. Later, he shifted to Banāras (modern Varanasi) and Murshidābād. Actually, he was appointed first Chief Justice (*Ṣadr as-Ṣudūr*) at the court of the Raja of Banāras and later served also Nawāb of Murshidābād. He died on his way to his hometown Jaunpūr, in Dā’ūdpur city, in A.H.1279/A.D.1862.

Scientific Writings: Major Works

1. “On Problems of Astrolabe for Friendly Companions” (*Anīs al-Aḥbāb fī Bayān Masā’il Aṣṭurlāb*) written in 1818. Its manuscripts are extant in KhB (Patna) with two copies. Ms.1063 is a copy of 1830.

To note are the abbreviations of the various libraries/manuscripts collections: **ASB** (Calcutta): Library of the Asiatic Society of Bengal. **APSCL** (Hyderabad): Andhra Pradesh State Central Library (formerly *Āṣafiyah*). **BM** (London): Library of the British Museum (Oriental Section). **IOL** (London): India Office Library. **KhB** (Patna): Khuda Bakhsh Oriental Public Library. **MAL** (Aligarh): Maulana Azad Library (Aligarh Muslim University). **NMPL** (Murshidabad): Nawab of Murshidabad Palace Library. **PPL** (Lahore): Punjab Public Library, Lahore (Pakistan). **SJM** (Hyderabad): Oriental Manuscript Collection in Salar Jung Museum. This tract is a Persian commentary on the Arabic Treatise on Astrolabe by Bahā'uddīn Al-ʿĀmilī (d. 1621), whose treatises on astronomy and mathematics in Arabic had been very popular in textbooks in Indian Madrasas. The author states that the original Arabic text was too difficult to understand and hence he wrote this commentary, explaining the method of construction and working of the astrolabe. The tract contains also a section on geometrical and astronomical preliminaries.

2. "Compendium of Mathematical–Astronomical Sciences" (*Jāmiʿ Bahādurkhānī*) or "Key to Astronomical Observations" (*Miftāḥ al-Raṣad*) in Persian and written during 1832–1833. It was dedicated to the patron of the author, Rāja Khān Bahādur Khān. The Compendium was lithographed originally in 1835 in Calcutta and reprinted in Tehran in 2008. Its few manuscripts are extant in BM (London) with excerpts only; in SJM (Hyderabad), scribed in 1871; in ASB (Calcutta) in the Curzon collection; and in KhB (Patna). A complete manuscript but undated is also extant in PPL (Lahore), which is excellently written and contains very good diagrams of astronomical instruments dealt in separate chapters. Copies of the printed text are extant, one each in BM (London), NMPL (Murshidabad), and PPL (Lahore) and 3 copies in KhB (Patna), 2 in

MAL (Aligarh), and 2 copies in APSCL (Hyderabad).

- This encyclopedic work comprises six books, each of which is divided into chapters. The chapter on mathematics comprises sections, one for each of its branches, e.g., on trigonometrical functions with solutions of both plane and spherical triangles. The part on astronomy deals with the science of astronomy (*ʿIlm-i Hayʿat*), astronomical tables (*Zīj*), and almanacs (*Taqwīm*). Although mathematics spans over 63 % of the text and the remaining 37 % deals with astronomy, the author emphasized the latter, as is apparent by the second title of this Compendium. Besides the description of Graeco–Arab geocentric model of the planetary motion, he also includes European astronomy, e.g., the heliocentric system of the planets (p.476 *et seq.*) with a clear diagram (Fig. 1), showing also the orbit of Uranus and of minor planets such as Pallas and Ceres, with satellites around the different outer planets. He also explains gravitation (*Jadhb* or *Anjadhāb* in Arabic). In the last book, Ghulām Ḥusain deals with 12 astronomical instruments, each in one chapter and illustrated with a diagram. Two of these are of modern European origin, namely, the compound telescope (*Minzār-i Murakkab*) with a mounting system and reflecting sextant (*Sūdus-i Inʿikāsī*). I may add here that late Prof. Mahdi Ansari Farangīmaḥlī (Aligarh) possessed a unique celestial globe manufactured by Ghulām Ḥusain Jaunpūrī, which is dated 1231 A.H./ A.D. 1816, described by Ansari and Sarma (1999/2000, pp. 82–84).
3. *Zīj-i Bahādurkhānī* (in Persian) are astronomical mathematical tables, which Ghulām Ḥusain compiled during 1838–1841 by the order of Rāja Khān Bahādur Khān to whom it was dedicated. Its second title is "Book for the Benefit of Syllabus/Teaching" (*Kitāb Ifādāt-i Niṣāb*) indicating the purpose of writing this *Zīj*. It was lithographed in India during 1855–1858 at Banaras and reprinted in Tehran, 2009.

Ghulām Ḥusain Jaunpūrī, Fig. 1 This heliocentric diagram (p. 474) depicts the orbits of planets and their satellites (*Tawābī*) according to the following scheme: Sun, Mercury, Venus, Earth (1 satellite/moon), Mars, Pallas,

Ceres, Jupiter (4 sat.), Saturn (7 sat.), Uranus/Jārijis (6 sat.). The author states clearly that the Europeans have been able to observe these satellites with the help of telescope

Ghulām Ḥusain explains the reason for compiling his *Zīj*:

Using the fine and accurate instruments of European scholars, a few of which are available in the Rājā's kingdom, I can find by observation spread over a number of years the discrepancy between the observed (*Marṣudah*) position of the celestial bodies and their calculated (*Maḥsūbah*) ones on the basis of the *Zīj-i Muḥammad Shāhī* [ZMS]. [The ZMS was actually compiled by Mirzā Khairullāh Muhandis in the eighteenth century under the supervision of Raja Sawa'i Jai Singh (d. 1743) by the order of Mughal Emperor Muḥammad Shāh (reigned 1719–1749), cf. Ansari (2007) for details].

And therefore I have compiled this *Zīj* based on our own nine-year long observations of eclipses, occultations of planets . . . , so that any one [interested] can calculate, by using these tables, the longitude of the stars and planets, the occurrence of solar eclipses, crescent visibility . . . year by year for a long time. (p. 2)

This *Zīj* consists of one introduction (*Muqaddmah*) and seven discourses (*Maqālah*), each of the latter comprising several chapters (*Bāb*). The author deals with 15 calendars, which include, besides the usual Islamic calendars, the Indian *Samvat* and *Shāka*, Akbar's *Ilāhī*, and Muḥammad Shāhī calendars. Actually, it is

a reworking or recension of ZMS based on Ghulām Ḥusain's own observations, in which the new elements of European astronomical knowledge were interwoven.

Minor Works

4. "On the Terminology of Almanac" (*Iṣṭilāḥāt-i Taqwīm*). Its manuscripts are extant in KhB (Patna), Curzon collection in ASB (Calcutta). This small tract comprises a preface and 14 short chapters with an epilogue (*Khātimah*). The author explains the technical terms used in the preparation of almanacs and method of their computation. Moreover, he complains about the sad neglect of astronomy in his times.
5. Persian translation of the Arabic version of *De Sphaera* of Theodosius (*Rā'iq al-Nuḥūs Tarjamah-i Ukar-i Thā'ūdhūsiyūs*), a unique MS of which is extant in APSCL (Hyderabad), Storey (p. 2, no. 2.3).
6. A commentary also on Naṣīruddīn al-Ṭūsī's recension of Euclid's geometry (*Tahrīr al-Uqlīdis*) with the Persian title: *Tabṣīrah al-Muhandis*. One manuscript is extant in the ASB (Calcutta), dated A.H.1245/A.D. 1830, and another in the private Library of the Raja of Banaras. This is the only work of Ghulām Ḥusain in Arabic.
7. "Warning to Repudiators" (*Tanbīhāt al-Munkirīn*) is a short tract written in A.H. 1238/AD1833, for which year the title is the chronogram. Its manuscript is extant in Ḥabīb Ganj collection of MAL (Aligarh). It was scribed in A.H.1268/A.D. 1852 and is of only 5 ff. Another manuscript is extant in KhB (Patna), of 10 ff, and was scribed in 1883. The author traces the reasoning underlying the geocentric stationary model of the universe and discusses the proofs of the motion of the Earth according to Pythagoras and European astronomers.
8. "Key to Mathematics" (*Miftāḥ al-Riyādī*). It is a small tract of 38 ff on mathematics extant only in KhB (Patna); it is not dated.

Conclusion

Ghulām Ḥusain was primarily an astronomer and instrument maker. He possessed a small observatory in the Maharaja's castle at Tikari, where he possessed many astronomical instruments of his own making, including a couple of instruments of nineteenth-century Europe, e.g., sextant and telescope. From his abovementioned major works, I list the following important observations Ansari (2002b, pp. 257–258, 259, 260):

1. A comet observed at Banaras during 26 September to 5 October 1825.
2. A partial solar eclipse was observed on Friday, 8 July 1842, with the duration of 10^h 4^m 14^s.
3. A lunar eclipse occurred on October 1838 in Gaya (Bihar), at 8^h 8^m 11^s past noon.

Glass in China

Emily B. Curtis

Emily Byrne Curtis, Independent Scholar and Researcher, Hoboken, NJ, USA

Glass has always occupied a marginal position in China. From the earliest times, it has exhibited a varied composition reflecting the disparate sources for raw materials, and it was further complicated by the occasional mingling of western glass in the manufacturing process. For instance, chemical analysis of early glass artifacts found in China showed that they had been made with soda (SiO_2) and lime (Na_2O) of western Asian origins. The fact that these specimens came mainly from the coasts of Guangxi and Guangdong provinces in southern China indicated that this glass, in the form of ingots or finished products, was imported through the maritime route. Glass was also shipped in large quantities as cullet (glass lumps and discarded broken vessels), suitable for remelting and making new glass inexpensively. Thus, while it is not always possible to establish the uniqueness of Chinese glass from a chemical standpoint,

Glass in China, Fig. 1 Glass, inlaid “eye bead,” Warring States period (481–221 B.C.), L. 2.8 cm, D. 2.3 cm (Collection, Bristol Museums, Galleries & Archives)

analyses have been able to shed light on its various components and provide us with a time line for its evolution (Figs. 1, 2, 3, 4, 5, 6, 7, and 8).

The glassmaking process itself can be roughly divided into two phases, the first of which was reducing the raw materials to a powder after which they were fused in furnaces capable of reaching high temperatures. In the second phase, the molten glass (called metal) was ladled or poured into molds and pressed, blown, or drawn. The finishing process could be done either at the original glass workshop or carried out elsewhere. Also, it might suggest that a subdivision of labor existed between craftsmen who knew how to mix the raw materials and manipulate the furnaces and other artisans who were skilled in blowing or carving the glass.

The Initial Stage

Studies of Chinese glassmaking were initially limited to literary sources which placed the beginnings of the craft in the fifth century B.C.

Emily B. Curtis is retired.

Glass in China, Fig. 2 Glass, press-molded hairpin with dragon head, Ming dynasty (1368–1644), L. 11.0 cm, W. 1.7 cm (Collection Bristol Museums, Galleries & Archives)

Glass in China, Fig. 3 Glass, molded as a recumbent boy supporting his head on his hands, Qing dynasty (seventeenth/eighteenth century), L. 11.9 cm (Collection, Dr. Alan E. Feen)

However, more recent archaeological excavations in China have uncovered evidence which indicates that production may have started in the late Zhou dynasty (1046–221 B.C.). The shapes of the excavated round and cylindrical glass beads indicated a definite influence from jade and stoneworking, and western Zhou glass may well be the first glass made in imitation of jade. However, since the chemical compositions for some of the beads are dominated by SiO_2 , and there are large amounts of crystalline quartz present, some scholars argue that this material is not really glass but faience. The sword decorations generally proved to be transparent glasses of the calcium silicate (X-CaO-SiO_2) or potassium calcium silicate ($\text{K}_2\text{O-CaO-SiO}_2$) variety.

Glass in China, Fig. 4 Glass, brush washer of opaque ivory with ruby-red carved overlays, lip rim with incised four-character Qianlong mark (1736–1795) on rim, D. 8.3 cm (Collection, Dr. Alan E. Feen)

While glassblowing was invented in the Middle East, perhaps in Syria, about 50–25 B.C., this technique developed later in China. Given that Bactrian glassblowers are believed to have been working at Datong, Shanxi province, during the Northern Wei (386–581 A.D.) period, the question arises as to when and if they passed on this technique to Chinese craftsmen. Therefore, the glass vessels from this period, which were found in a stupa in Jingxian, Hebei province, have been considered as important. The cache contained three gourd-shaped bottles, two other bottles, and a monk's alms bowl. All of them were blown of domestic (Chinese) glass. This was an important turning point in the history of Chinese glassmaking, because it made mass production possible and glass products less expensive.

Glass Workshops at Boshan

Written records inform us that glass hair clasps were produced in the Tang dynasty (618–907 A.D.) and that in the Song dynasty (960–1279

A.D.), the majority of women were wearing hair ornaments made from glass. Some examples of rings and hairpins in opaque off-white or turquoise glass may well be products of the glassworks in Zibo, Shandong.

The remains of an ancient glass factory, dating to at least the late Yuan to early Ming, were discovered in 1980s by the edge of the Shaofu River in Boshan (Zibo). The subsequent excavation of this site uncovered pieces of glass, the remains of clay pots, their covers, and some 20 furnace pits arranged in a line. Chemical analyses of the glass shards revealed that they

contained a high level of calcium and a low level of lead. When tested, a sample of blue opal glass was found to contain fluorine, and the lime found in this specimen could be accounted for by the presence of fluorspar. It was determined that the melting furnaces had been fueled by coke, which is also noted in ancient Chinese literature.

Two basic ways of forming glass were employed. Items like hair clasps were made from glass rods or tubes by a secondary process; they were reheated and then formed. Button-like ornaments were made by reheating and molding. These glass objects represented an alternative to jade, a much cherished and more expensive material. They also represented an expanded repertoire since many of the glass objects found in earlier burial contexts were made with shapes similar to their jade counterparts. This imitation was intended to replicate the shape and significance of jades – a major distinctive feature of Chinese glass and also one of the distinguishing marks between Chinese and western glassware. The unusually high concentration of barium oxide (BaO) in the composition of early Chinese glass produced a certain turbidity in the metal which might have been regarded as desirable by the craftsmen since it gave the glass a jade-like appearance. This trait is quite apparent in opaque, white glass artifacts.

Sun Tingquan's *Yanshan zaji* (*Mt. Yanshan Records*) dates to 1665. In it Sun gives a systematic and informative account of the glass materials, properties, coloring, melting times, tools, products, and distribution at Boshan. According to Sun, the glass was made entirely from local

Glass in China, Fig. 5 Glass, aventurine, pierced and cut to resemble a scholar's rock, H. with stand 9.2 cm, nineteenth century (Collection, Robert H. Blumenfeld)

Glass in China,

materials such as feldspar, fluorspar, quartz, and niter. He also comments upon the creativity of the craftsmen in contending with a lack of sophisticated tools and instruments.

What is of particular note here is that Boshan was a major glassmaking center which, due to a series of natural disasters, had ceased operation by the end of the Ming dynasty. Under the patronage of the Qing emperors, it was able to resume its role as a center of Chinese glassmaking, supplying both materials and craftsmen to the imperial glass workshop; it remains active in present-day China.

Imperial Glassmaking

Qing dynasty (1644–1911) glass deserves an important place in the history of Chinese glass. In the 35th year (1696) of Kangxi (r. 1662–1722), an imperial glass workshop was established under the direction of Kilian Stumpf, SJ (Ji Lian). Under the patronage of Qing rulers, many new varieties of glass were made, and it was an outstanding period of artistic accomplishment. K_2O and PbO , which were used as fluxes in ancient Chinese glasses preceding the Qing dynasty, proved to be the main fluxes of the glasses analyzed of samples in the Beijing Palace Museum. The raw glass materials used by the imperial workshops included “horse-tooth stone,” saltpeter, borax, white arsenic, and fluorspar. The saltpeter referred to should be potassium nitrate, which was used also as a raw material in the fourteenth-century potash-lime glass in Boshan. According to these findings, the MgO content of the glasses made from the saltpeter was very low (below 0.5 %). “Horse-tooth stone” could be feldspar. Qing glassmaking was also influenced by western technology because some glasses contained B_2O_3 and As_2O_3 , which were introduced as borax and white arsenic, respectively. The colorants included oxides of copper, iron, and cobalt. Spectral analysis showed that the red glass on the cameo samples contained a small amount (about 0.01 %) of gold.

Another important innovation was the application of western technology to make gold ruby glass. This variety can be made when there is colloidal

gold present in the glass batch. The red color is caused by selective light scattering of the gold particles in the glass. This process was successfully transferred from the court to Boshan by 1820 and made its way to Guangzhou (Canton), which brings up the topic of glassworks in other areas of China.

Regional Glass Workshops

Glassmaking in Guangzhou is thought to have commenced in the late seventeenth century.

However, their art glass was not held in high repute by Chinese writers and often fell below the Qing court's standards. Despite this, the city was an important source of skilled artisans who staffed the imperial glassworks, and records of their employment in this capacity date as early as 1708. On the local level, Guangzhou craftsmen were occupied primarily with making sheet glass for spectacles, mirrors, and windowpanes.

Interestingly enough, historians in Yangzhou credit the rise of the craft in their area to the influence of Guangdong glassworkers and go on to attribute the development of a local style of trailing cameo glass to their own artisans. In common with "Peking Glass" at this time, glass-making in either locale did not include the initial process of glass melting, but was solely the fabrication of objects from glass ingots. These ingots were known as *liao qi*, implying glass made with Shandong (Boshan) *liao*. This practice also seems to apply to a very distinctive group of wares (mainly snuff bottles) identified by the term "Yangzhou School."

According to textural references, Yunan specialized in making a type of lampshade (*liaosi deng*) from thin glass rods, which were widely used among the elite. The history of its glass beads is more difficult to chronicle, leaving one to suggest that, since Boshan was known to have exported glass rods to all parts of China, Yunan's glass was fashioned from them.

Glass artisans in Suzhou specialized in manufacturing glass chimes and used recycled glass for making lampshades with painted designs on the interior. Given Suzhou's renown as a center for hard-stone carving, there is the

possibility that its glassworkers also fashioned carved glass objects for the court and the general populace. As to the source for its glass material, this too awaits further research and study.

New Methods of Décor

The influx of western glassmaking technology allowed Chinese craftsmen to produce art glass in a wider range of colors and employ new methods of décor. Among the latter are:

- Aventurine glass – Known in Chinese as "gold star" (金星, *jinxing*) glass; this variety was a specialty of Venetian artisans and a particular favorite of imperial patrons.
- Diamond-point engraving – The use of a diamond point to produce linear drawing on glass was introduced to the imperial glassworks in the late seventeenth/early eighteenth century.
- Enameled glass – In this decorative technique, a mixture of colored powdered glass was allied with an oily medium and fused to a glass object in a furnace. This style of décor evolved during the Qing period.

Other methods of décor which may well have been derived from European examples and glass-makers are:

- Multicolor overlay – A method whereby a blank is overlaid with two or more different colored layers.
- Swirled glass – This effect is achieved by gathering up small colored glass pieces onto a molten lump attached to a blowpipe and fused in a furnace.
- Threaded glass – Molten colored glass in string forms is applied to a hot core to be rolled around inside the furnace for fusion, resulting in parallel segments of contrasting colors.

Contemporary Glassmaking in China

All imperial glassmaking had ceased in 1860. This prompted the Qing court to monopolize the

nation's glassmaking by establishing state-run companies and restricted the procurement of glass ingots from Boshan. These actions severely depressed Boshan's economy, and in 1902 thousands of its local craftsmen staged an uprising. This was suppressed, and Boshans' glass artisans were hard-pressed to make a living until after the fall of the Qing dynasty (1912). Many glass-makers survived in the ensuing years by concentrating on making brightly colored wares, often in imitation of imperial pieces. The situation gradually improved and present-day China is experiencing a renaissance in its arts and crafts. Institutions such as the Shanghai Museum of Glass not only feature exhibitions of ancient and contemporary glassworks but also focus on all aspects of this art which has encouraged contemporary glass artisans to explore and expand the range of their creations.

Glass in Egypt

Chloe Duckworth

School of Archaeology and Ancient History,
University of Leicester, Leicester, UK

The Invention of Glass

Glass was first produced deliberately and consistently in Mesopotamia sometime between c. 1650 and 1550 BC. There is some scattered evidence for prior glassmaking, largely in the form of beads (see, e.g., Grose, 1989, p. 45), but much of this material was most likely the accidental by-product of other pyrotechnological processes, namely, faience production and metal smelting. The latter sometimes resulted in highly colored vitreous slags, examples of which can be dated back as far as the third millennium BC (Schlick-Nolte & Lierke, 2002, p. 15). The earliest glass vessels were relatively small, the majority being under 15 cm in height, and were employed as perfume and cosmetic containers. Glass also found use as inlay, where it was arranged alongside semiprecious stones such as turquoise and lapis lazuli and precious metals such as gold. Most early glass was highly colored, and the Egyptians particularly favored dark and light blue, yellow, white, and red opaque glasses. Colorless glass was extremely rare prior to the mid-first millennium BC (Fig. 1).

The accidental production of glass during the practice of other high-temperature industries noted above may have provided the early impetus for its production as a material in its own right. Glass was related to several contemporary industries: metal extraction, as glassy slags are often a

Glass in Egypt, Fig. 1 Egyptian core-formed unguent container, housed in the Classical Museum, University College Dublin

by-product of metal smelting; stone working, with many stones and semiprecious stones having conceptual links with glass; and the production of faience, which is also an artificial material and which uses the same basic ingredients as glass, albeit in very different proportions, as shown in Table 1. Largely due to the use of these ingredients, faience is generally credited as the material most likely to have directly given rise to glass (Tite, Shortland, & Paynter, 2002). Given the close proximity of many craft activities in both Egypt and Western Asia during the Late Bronze Age, however, it is quite possible that glassmaking did not develop out of a single one of these industries, but may have been influenced by several.

The Earliest Glass in Egypt

The earliest evidence for glass in Egypt all points to a Mesopotamian origin, and direct parallels with Mesopotamian material can be found among Egyptian glass from the fifteenth century BC.

Glass in Egypt, Table 1 Typical proportions of the major constituents of Egyptian and Mesopotamian faience and glass in the Late Bronze Age

	Silica (crushed quartz) (%)	Lime (%)	Alkali (soda and potash from plant ashes) (%)
Faience	93–98	1–5	0.5–3
Glass	60–67	6–9	16–22

Examples of probable Mesopotamian imports come from the tomb of the three foreign wives of Tuthmosis III. For example, a button-based glass goblet from the tomb is comparable in shape and decoration to items from Nuzi. Similarly, a glass flask (KV 36) from the tomb of Maiherperi, dating to late in the reign of Tuthmosis III, has close parallels in material known from Tell Brak, associated with tablets thought to date to the fifteenth century BC (Lilyquist, 2005, p. 63).

As noted by Moorey (2001, p. 3), the Hurrian-speaking people of the Kingdom of Mitanni are known to have been particularly instrumental in a series of technological innovations during the Late Bronze Age, and it is thought that one of these was the development of glass production. Oppenheim (1973, pp. 263–264) has noted that the terms *ehlipakku* and *mekku* are thought to refer to glasses that are Hurrian and West Semitic, respectively, supporting the theory of northern (upper) Syria as the nexus for glass technology.

How exactly the knowledge of glass production was first obtained by the Egyptians is unclear, but given the atmosphere of secrecy surrounding important craft processes, perhaps the most plausible hypothesis which has been put forward is that foreign craftsmen were captured in campaigns (probably those of Tuthmosis III) and subsequently led the Egyptian glassworking industry (Oppenheim, Brill, Von Saldern, & Barag, 1970; Petrie, 1926, p. 229; Shortland, 2001, p. 219). Most of the earliest vessels known in the Egyptian style, however, were cold worked in the manner of stone, and it is equally possible that the first glass workers to be introduced came slightly later, perhaps during the reign of Amenhotep II, bringing a fully formed knowledge of hot-working glass techniques.

In any case, glassworking was certainly firmly established by the reign of Tuthmosis IV (early fourteenth century BC). This is the first period in which cobalt (responsible for a striking blue color in glasses and accessible in the Egyptian territory) was used extensively as a colorant, suggesting the primary production of glass within Egypt, and coinciding with the establishment of a standard repertoire of vessel forms and heralding the start of the Egyptian glass industry proper.

By the end of the fourteenth century BC, the various regions in which glass was present had developed localized styles, such as the characteristic relief beads of the Mycenaean world, suggesting that glassworking was being practiced locally. The evidence does not, however, imply that glass was being made (fused from raw ingredients) in the Mycenaean territory. Indeed, it seems that the Aegean had become the first – though it was by no means to be the last – importer of Egyptian glass. The discovery of 175 glass ingots in the cargo of a late fourteenth-century BC shipwreck off Uluburun, Turkey, in a shape and size with clear parallels at Egyptian production sites, suggests that glass was being transported from Egypt to Mycenaean Greece, and recent isotopic analyses (Henderson, Evans, & Nikita, 2010) have confirmed that glass was probably entering the Aegean from both Mesopotamia and Egypt.

Egyptian Glass Technology

Despite the links between primary glass production and other applications of pyrotechnology such as metalworking noted above, the very first glass does not seem to have been cast or worked while hot. Instead, the principles of stone working were applied to the production of glass vessels, with glass chunks or ingots being treated as blanks to be laboriously ground and polished. The later appreciation that glass could be manipulated by heat meant that vessels and beads could be produced by casting or by various methods involving coating a removable core of material with glass and applying trails or blobs of another

color of glass onto this base, a practice known as “core forming” (Fig. 2).

When exactly this transition to core forming was established is difficult to determine with precision. In part this is no doubt due to the poor preservation of glass in most climates: the arid Egyptian climate is particularly, and exceptionally, favorable to the preservation of early soda-lime-silica glass. Fragments of core-formed glass vessels have been found at Alalakh in levels dating to 1600 BC, suggesting that the knowledge of core forming was already known in northern Mesopotamia at this early stage (Nicholson, 2007, p. 3).

In any case, the superior preservation of Egyptian glass, coupled with its continued high status throughout the New Kingdom, means that the Egyptian evidence, though slightly later in date, is far more abundant than that from Mesopotamia. From the latter, we have possible – though somewhat difficult to interpret – recipes for the production of colored glasses (see Oppenheim et al., 1970). Egypt, on the other hand, has provided at least one and most likely two examples of early glassmaking sites; these are the earliest known in the world. Primary glass production sites are not frequent finds, and it is often difficult to identify them (one reason for this is the recycling of scrap and waste glass and the lack of significant by-products such as the slags associated with metal production), so the two examples discussed below provide a rare insight into the earliest glass production.

The first of these glassmaking sites was found at the mid-fourteenth-century BC city of Akhetaten, Amarna. Amarna was originally excavated in the 1890s by W. M. F. Petrie, who recorded the presence of semi-fused glass and crucible fragments with adherent glaze at the site, though the location of his hypothesized “glass factories” was not precisely recorded. More recently, excavations at site 045.1 revealed a complex of furnaces or kilns, at least one of which has been argued to have been used for primary glass production (Nicholson, 2007) and which yielded a semi-fused material indicative of an intermediary stage in glass production (Jackson & Nicholson, 2007). Despite this, there

Glass in Egypt,

Fig. 2 Fragments of Egyptian core-formed vessels, 1400–300 BC, housed in the Classical Museum, University College Dublin

G

has been significant debate as to whether the evidence from Amarna points to the primary production of glass, to glass coloring, or to the re-melting of glass made elsewhere for the purpose of working it. Following the initial excavation of the furnaces at site 045.1, Nicholson and Jackson (1998) conducted a reconstruction glass-making experiment in a replica furnace, finding that it was possible to directly fuse glass from its raw ingredients in such a structure. It should be emphasized that this evidence alone does not prove that glassmaking was necessarily practiced at the site, only that it could have been. Perhaps more conclusively, Smirniou and Rehren (2011) have reexamined the evidence from Petrie's excavations and have analyzed several examples of "semifinished" glass, strongly indicative of primary production of glass at the site (Fig. 3).

Qantir, in the northeastern Nile Delta, was the site of an industrial estate created in order to serve the building works at nearby Pi-Ramesses, the thirteenth-century BC capital of Ramesses II. The most extensive industrial feature at Qantir is a large bronze-casting factory, but recent excavations have revealed that this was accompanied by a number of works for smaller-scale high-temperature production, perhaps placed together due to their common use of copper. Among these smaller works is evidence for the primary production of red opaque glass. This includes 40 large crucible fragments (and several hundred

Glass in Egypt, Fig. 3 Fragments of glass canes, which would have been heated and wound around the core to produce the vessel's body and its trailed decoration, uncovered during Petrie's excavations at Amarna (fourteenth century BC). All fragments housed in the Classical Museum, University College Dublin

smaller ones), many with traces of red glass adhering to them and the remains of a lime parting layer (Rehren & Pusch, 2005, p. 1756); fragments of uncolored glass; and a complete ingot of red glass colored by adding copper and heating under a reducing atmosphere (Rehren, Pusch, & Herold, 1998, p. 227). The size of the crucibles was standardized and their interior dimensions match that of the ingot from the site. No remains of secondary glass production – that is, working of glass into objects – have been found at Qantir,

and only a few isolated fragments of blue glass have been found in addition to the red glass which dominates at the site (Rehren & Pusch, 1997, p. 136). Red glass must have been difficult to make due to the need to maintain a reducing (oxygen-free) atmosphere, so it is perhaps unsurprising that this site, at least, is specialized in the production of this color of glass.

Other sites yield evidence of secondary glassworking. As well as indirect evidence, such as the presence of regional styles in finished glass objects, glassworking can be indicated by the presence of rods or canes of colored glass used in core forming and decorating glass objects. Such canes have been found at Amarna, Malkata, Lisht, and Menshiyeh (Abydos), in Egypt, and at Tell Brak, in Syria.

The Perception of Glass

Also of interest is the way in which this earliest glass was perceived and valued in Egypt. In the Annals of Tuthmosis III at Karnak, glass is listed directly below gold and silver and alongside precious stones including lapis lazuli and turquoise, the former of which was highly prized and had to be imported from a great distance. The high value of glass seems to continue into at least the fourteenth century, at which time it is found as an inlay alongside these same materials (gold, lapis lazuli, turquoise) in the mask of Tutankhamen.

It is thus apparent that glass was of high value throughout the first few hundred years of its use in Egypt. Less clear, perhaps, is why a substance which was made from relatively abundant raw materials was so highly prized. One explanation

is that the color and material properties of glass were at the center of its value (Duckworth, 2012). For example, the cobalt required to produce the highly prized deep blue of much early glass most likely had to be obtained via dedicated royal expedition. In other cases, difficulty of production may have added value, as with the creation of red glass which required heavy control over the furnace atmosphere. The potential of glass to be worked while hot and its transportation in ingot form may have conceptually linked it with metals, while its visual appearance and the linguistic terms used to describe it suggest that it was also related to semiprecious stones. It is possible that the production of glass itself was ritually significant – a demonstration of human control over the chaos of nature – and that the artificiality and base origins of the material, far from lowering its value, were at the very root of its power as a transformed material.

The Later Glass Industry

An interesting aspect of ancient technology in general, and glass production in particular, is its propensity for conservatism (see, e.g., Sode & Kock, 2001). This makes sense when we consider that the alteration of just one variable in ancient glassmaking could have led to the failure of the entire batch and would constitute an enormous waste of resources, particularly expensive fuel. In addition to being relatively conservative, glass production has traditionally been highly secretive (Fig. 4).

It is the combination of these factors, perhaps, along with the ready availability of the relevant

Glass in Egypt,

Fig. 4 Fragments of millefiori glass vessels, third century BC to first century AD. All fragments housed in the Classical Museum, University College Dublin

raw materials in Egypt and along the Syro-Palestinian coast that are behind the continued significance of these areas in glassmaking from the mid-second millennium BC to the later second millennium AD. Egyptian glass was highly prized in the Hellenistic period, with Alexandria becoming a key center of glass production and remaining so for hundreds of years, as recorded by Cicero in the first century BC and Strabo in the first century AD. Glassmaking flourished under Islamic rule, with the Muslim capital at Fustat, later Cairo, becoming a new center of glass production. By the late thirteenth century, the Egyptian and Syrian gold-painted and enamelled mosque lamps were among the most highly prized objects in the Islamic world (Carboni, 2001, p. 199; Pinder-Wilson, 1991). Knowledge of glassmaking and working would have been handed down within the family, but even within this atmosphere of conservatism and secrecy, there must have been significant scope for innovation and change. Egypt's continued place at the forefront of glass production for millennia is testimony to this.

Development of Glass in India

Indian Glass

Foreign travel accounts like Pliny's *Naturalis Historia* (73–77 AD; translated by Bostock and Riley as *The Natural History of Pliny* in 1890), *Periplus Maris Erythraei* (considered to be earlier than *Naturalis Historia*; translated by Schoff as *Periplus of the Erythrean Sea* in 1912) and *Geography of Strabo* (17–23 AD; translated by Jones and cited in Majumdar, 1960, pp. 279, 394) considered Indian glass to be of high quality as it was made of pounded quartz rather than silica. It has long been suggested that this may have been the reason behind the high silica content in ancient Indian glass (Stern, 1987, p. 28). In Gudur (Andhra Pradesh), the government glass factory till recently produced glass from crystal. Dr. Brill of the Corning Museum believes that glassmakers throughout Iran, Mesopotamia, and central Asia (cited in Stern, 1987, p. 28) routinely used pebbles instead of sand as the source of silica. In fact, in a Herat (Afghanistan) factory in 1977, the glassmakers still used pebbles collected in the riverbed as their source of silica.

Although glass was commonly made in the west Asian Bronze Age, there is some

controversy concerning its manufacture in the Indus valley civilization (Glover & Henderson, 1994). Some scholars have tried to trace the origin of Indian glass to the Harappan civilization on the basis of finding glazed pottery and quartz beads. Harappans made glazed pottery, which is ceramic with a thin layer of glass on the surface (Tite, Freestone & Bimson, 1983). Though no true glass has been found in India from the Protohistoric periods at Mohenjodaro and Harappa, the second millennium BCE saw its people able to mould and fuse excellent articles of faience and glazing their quartz beads with frit, a material similar to glass. All three materials—glass, glaze, and faience—consist of silica and lime, although special modern glass need have neither. Glass and glazes always contain soda or some or the other alkali, whereas faience generally contains only very small quantities of soda. In the evolution of glass, frit, faience, and glaze might have signified certain stages of development (Beck, 1934; Biek & Bayley, 1979; Brill, 1963, p. 120; Forbes, 1957, p. 223).

Glaze

There is little doubt that glass was an outcome of glaze. Glass and glazes are chemically identical but they are worked and used differently (Forbes, 1957; Tite et al., 1983). The glazing technique marks the emergence of the first glass or synthetic material (de Barthelemy & Bouquillon, 1994). However, a glaze is a glassy layer applied to a core or base of some other material. This is in some cases mixed with the material before firing and in many cases applied to the body after firing. In the fourth millennium BCE glaze was used extensively within the context of the Badarian civilization in Egypt, the Jemdet Nasr period in Mesopotamia and in the third millennium BCE, the Indus valley civilization. The method of grinding quartz and mixing it with a little alkali before firing and producing faience occurred somewhat later in Egypt, in the early pre-Dynastic period (Forbes, 1957; Lucas, 1926). Marshall (1931, pp. 578, 582, 692) states that the glazing of pottery is an Indian invention and a craft which appears to have been practiced for the first time on the bank of Indus. No

example of it has come to light in Mesopotamia before 1000 BCE, nor in Egypt before the Roman period, although in Nubia there is said to be evidence of glazed ware as early as the twelfth dynasty (1991–1928 BCE). On the strength of the available material at Mohenjodaro and Harappa, Marshall (1931) went on to say that they are so closely allied to glass that it hardly seems possible that glass could have long been delayed. Bhardwaj (1979, p. 31) thought that the four pieces of glazed pottery found at Mohenjodaro were the handiwork of a potter who was well acquainted with the process of glazing and able to carry it to a high degree of perfection. High temperature stoneware bangles and some glazed pottery have also been recorded from Lothal, Bhagwanpura, Sanghol, Banawali, Bara, Ropar, Chanhudaro, Hulas, and Mithathal (Dayton, 1989).

Faience

Faience is nearer to glass in the process of evolution. It is reported from many ancient sites and is likely to have been the predecessor of glass (Brill, 1963, p. 120). In the archaeological sense it is generally agreed that faience consists of a lightly sintered core of crushed quartz grains coated with a translucent blue-to-green glaze, both fluxing due to soda. Such material needs a firing temperature of some 1000 °C and a certain amount of sophistication in making it (Biek & Bayley, 1979, p. 3). Crystalline quartz grains with a small amount of glassy material predominate in the case of faience. A few simple variations, whether accidental or deliberate, would have resulted in true glass (Basa, 1991). Stone and Thomas (1956, p. 37) proposed that glass could be produced by heating faience too much or for too long, while adding a little surplus of alkali. They further suggested that it is most probable, then, that the faience makers found this out by simple observation and so became the first makers of real glass. Forbes (1957) and Bhardwaj (1979) have proposed to call most of ancient objects dubbed faience to be glazed siliceous ware, as they have a body consisting of powdered quartz covered with a layer of glaze. This material has been reported from most of the ancient civilizations

including Egypt, Mesopotamia, and India (Lucas, 1926; Sofianopoulos, 1952). Faience was certainly made in India and fashioned into a variety of objects such as amulets, bangles and inlay, segmented beads, spindle-whorls, fluted disc beads, seals, animal figurines, and pots. In the Indus valley itself the people of Mohenjodaro and Harappa are known to have made extensive use of articles from faience, a composition resulting from powdered quartz grains fused at low temperature with the addition of lime. Some of the articles like beads and inlays were found treated with a glaze or frit which does not materially differ from glass. Marshall (1931, p. 683) and Mackay (1931, pp. 576, 578 and 582) are of the opinion that though no true glass has been recovered from Mohenjodaro and Harappa, the authors of these cultures had perfected a composition which very nearly approached glass. Experiments conducted by McCarthy and Vandiver (1991) have revealed that the Harappan faience has a quite dense body with a continuous glassy phase and a relatively thin skin of glaze. Intentional addition of glass frit and clay are postulated. The Harappan faience bodies are particularly strong, compared with contemporary faience from west Asia and Egypt. A similar technology is not found in Egypt until much later during the New Kingdom, about 1450 BCE.

Brill (1987, p. 2) gives two reasons in support of the belief that glassmaking grew out of faience manufacture. (1) Both processes involve the pyrotechnology of the same materials (silica and alkali), and (2) faience was made for some fifteen centuries before glass was made. In this regard, the data gathered at Mehrgarh and Nausharo are of great interest since they allow the study of the local evolution of the glazing techniques through time, from the Chalcolithic to the Mature Indus period (de Barthelemy & Bouquillon, 1997, p. 63).

Ancient Indian Glass

Bhardwaj (1987) and Singh (1989), on the basis of glazed pottery from Mohenjodaro, have argued that the Harappans were aware of glass making. Bhardwaj (1987) regards a number of vitreous materials unearthed from Mohenjodaro

as weathered unworked glass, but more finds from well-dated contexts are needed before we can be sure that the Harappans had truly mastered the secrets of glassmaking (Singh, 1989), and it is possible that glass could have decomposed to the point where it looked like faience.

Singh (1989) cautioned about the possibility that some glass beads might have been classified wrongly as stone beads. Even if the Harappans had this knowledge it seems to have been lost with the collapse of the urban Bronze Age civilization, and the subsequent finds of glass from the subcontinent come only with the Harappan-PGW (Painted Grey Ware) overlap phase at Bhagwanpura in Haryana, datable to about 1450–1200 BCE (Joshi, 1976). From this time onwards, glass beads and bangles were regularly made in many parts of the subcontinent (Lal, 1987). However, here thorough investigation of faience objects from Chalcolithic sites is required as they are reported to have yielded an enormous quantity of burnt steatite and paste, sometimes also glazed. Here it is important to mention that some of the beads that had been interpreted as shell beads (Casal, 1949; Wheeler et al., 1946) have now been identified as corroded glass (Francis n.d.). Too much soda will yield a kind of glass that will be easily corroded by water, though ancient glasses often have a large percentage of soda to achieve a low melting point (Forbes, 1957). In some cases faience is also wrongly identified as glass; for example faience excavated in Baoji and Fufeng country of China dated to eleventh to tenth century BCE was for a long time considered to be the earliest glass finding of China (Brill, 1995, p. 270).

From the analysis of 38 specimens found at Alamgirpur (undated), Brahmagiri (Megalithic and Andhra culture), Hastinapur (period V, eleventh to fifteenth century AD) and (period III, sixth to third century BCE), Sar Dheri, Arikamedu (ca. 200 AD), Kausambi (200 BCE–200 AD and 100–200 AD), Bihar (first to second century AD), Orissa (200 AD), Rupar (1000–700 BCE and 200 BCE–600 AD), Vankali (Sri Lanka 1200–1250 AD), Brill (1987) comments that if glass found in India has a high alumina content (Al_2O_3) i.e.,

3.5–4.0 % or greater, it probably was made in India and that a low lime content (CaO) can also be considered as evidence of local manufacture. Francis (1985, 1990a, 1990b, 1991, 1994, 2002, n.d.) based on his extensive work on Arikamedu glass beads, argues that glass beads from Arikamedu were made from local glass because of the presence of high potassium that was rare in the western glass of that period. In Egypt and the Roman Empire glass consisted of sodium oxide as alkali, whereas in India and Vietnam, as evident from Arikamedu (India) and Oc-Eo (Vietnam), both sodium and potassium oxide were utilized (Francis, 1990a). Lead as a coloring agent or opacifier in glass is found more in the West than in India. Glass from Khairadih, dated between 700 BCE to second century AD (Singh & Abdurazakov, 1988), Nevasa (Varshney et al., 1988) and Arikamedu (Glover & Henderson, 1994) are found to have low lime content. Furthermore, on the basis of scientific analysis of some of the early glass samples, Francis (n.d.) opines that both imported and indigenous glasses were used for bead production at Arikamedu and other contemporary south Indian sites.

In ancient India fragments of glass slag and other debris of glass production have been noticed at Khairadih, period II (IAR 1981–1982, p. 68; Singh and Abdurazakov, 1990), Kopia (Abdurazakov, 1987; Dikshit, 1969, p. 39; Lal, 1987, p. 45; Roy & Varshney, 1953; Sen & Chaudhuri, 1985, pp. 64–65), Rajghat (Narain et al., 1976; Singh, 1989) and Taxila (Marshall, 1951) in the North; Ahmednagar (Chaudhuri, 1986, p. 97), Bhokardan (Deo & Gupte, 1974, p. 197), Brahmapuri (Kolhapur) (Sankalia & Dikshit, 1952), Nevasa (Sankalia et al., 1960, pp. 355, 383–385), and Paunar (Deo & Dhavalikar, 1968, pp. 82–83) in the Deccan; Sirpur and Tripuri in Central India; Hulas Khera (Tewari et al., 1995–1996); Maheswar (Sankalia, Subbarao & Deo, 1958) and Nagra (Mehta & Shah, 1968, pp. 132–137) in the West; and Arikamedu and Karaikadu in the South. Thus, it is evident that ancient India was not only manufacturing by-products of glass but was also making glass for its use.

Regarding the glass furnace in ancient India, our information is meager. A solitary reference comes from Nevasa, where a glassmaking kiln dated to the period ca. third- and fourth AD was unearthed. It is a circular oven 2'–6" in diameter with 1'–7" depth and is made of burnt clay. Around it an abundance of bichrome glass, slag, lime, cow-dung, etc. was found (Sankalia et al., 1960). At one of the points near the periphery was a channeled projection evidently to insert the pipe for the bellows (Deo, 2000, p. 11). Chaudhuri (1986, p. 99) remarked that most of glass furnaces in ancient India are open-fired type, using solid fuel, and the melting was carried out in a clay pot.

Ancient Literature

Mention of glass (*kāca*) and its by-products, most prominently that of beads, occurs in early *Brāhmaṇical* (Sanskrit) and Buddhist literature. Chaudhuri (1986), Deo (1987, 2000), Dikshit (1964–1965, 1969, Ghosh (1924), and Mukharji (1888), list a few of them; for instance in the *Yajurveda* (c. 1200 BCE) *kāca* is mentioned as one of the articles of which female ornaments were made by means of stringing with gold thread. In *Śatapatha Brāhmaṇa* (c. 800 BCE), the word *kāca* refers to glass beads which were used for decoration of horses in the *Aśvamedha* sacrifice. There are references to women wearing glass beads and to the wearing of or threading of 101 beads of glass. The *Taittiriya Brāhmaṇa* also refers to the wearing of glass. Coming to the Sutra period (ca. 600 BCE), one comes across references to glass beads in the *Baudhayana Srauta Sūtra* and in *Manava Srauta Sūtra*. The *Māhavagga* section of the Buddhist text *Vinaya Piṭaka* (fifth to fourth century BCE) alludes to the use of shoes ornamented with glass as being forbidden to the Buddhist *bhikshus* (monks). The *Chullavagga* similarly forbids the use of glass bowls. One of the earliest South Indian texts, *Manimekalai* (3, 64), refers to *palingu*, meaning glass or quartz in Tamil, which is possibly a corruption of the Sanskrit word *sphatika*, although the prakrit *phalika* (quartz), occurs in the Bhattipruru inscription of the second century BCE (Srinivasan & Banerjee, 1953, p. 113).

Rāmayaṇa refers to the makers of glass, the '*kachakara*'. Kautilya's *Arthaśāstra* (third century BCE) alludes to the making of glass at two places. (1) *Adhikarana* 14, *Adhyāya* 1, *Sūtra* 12, says that in order to punish the enemy, obstacles like the smoke of Puti, Karañja leaves... as in the manufacture of glass, by burning cow dung etc., should deliberately be created. (2) Another passage in the *Adhikarana* 2, *Adhyāya* 14, *Sūtra* 45, though somewhat corrupt, refers to the process of making gold-foiled glass beads. It describes the piercing of glass beads in a molten stage for the purpose of setting ornaments and the setting of glass-fragments (*kṣepana*) in gold ornaments for the preparation of the glass gems. Amongst the various punishments inflicted for stealing, it is ordained that a person stealing articles made of copper, bronze, tin, glass and ivory was to be fined 46–96 *paṇas*. Glass is also mentioned in the *Māhābhārata*, and in *Yuktikarata*. The effects on the human system of drinking water out of a glass tumbler are stated to be the same as those of drinking out of a crystal cup. Some of the Puranas such as the Matsya, the Vishnu, and the Bhagawata, assigned to the Gupta period (third to fifth century AD), refer to *kāca*. *BṛhatSaṃhitā* (sixth century AD) also mentions glass. Apart from these, references to glass vessels for preserving medicines can be seen in texts like *Charaka* and *Śusruta Saṃhitā*. In the *Amarakośa* (seventh century AD) mention of glass vessels, cups and dishes are made. In later period, Somnath Kavi (ca. 1446–1539 AD) mentions spectacles in his *Vyasoyogi Charita*.

Spread of Glass in India

On the basis of glass findings at Taxila and Arikamedu, Marshall (1951) and Wheeler et al. (1946) thought them to be of foreign origin. On the contrary, typical Indian designs on some early glass specimens of Taxila, Mohenjodaro's glazed pottery and evidence of glass in the Chalcolithic level at Maski, and at Painted Grey Ware sites (supposed to be devoid of any foreign association) have led Dikshit (1969), Bhardwaj (1987), and Singh (1989) to argue for indigenous

origin of glass (Kanungo, 2000–2001, 2002a, 2004c). Deo (2000, p. 26) takes a middle path by mentioning that though much of the glass at Taxila was imported into India through its foreign settlers, there is reason to believe that some of the beads are indigenous. It is difficult to say how far early foreign contacts were responsible for the introduction of glass but the stray specimens reported do not point to anything definite.

The *Periplus* mentions Roman export of both raw glass and glassware. The ancient Indian literary records are silent on importing glass from the western world. However, the archaeological data on Roman glass in India strongly corroborates the references in the *Periplus* to glass imports into India (Gupta, 1997). Stern, (1986) suggests that it was convenient for Mediterranean shippers to bring raw glass to India as it served as good ballast for transport vessels. On reaching India, Mediterranean glass found a ready market because of the existence of a highly evolved glass working industry in the subcontinent. On their part, the Indians, besides marketing glass products of Roman glass in the domestic arena, exported the products to Southeast Asia and the Mediterranean. Probably, some of this glass really was imported, but there are good reasons for believing that much of this early glass was actually made in India (Brill, 1987, p. 2).

The Indians learned the technique of glass, probably independently, only around 1200 BCE. Since then evidence of glass has been unearthed from more than 200 ancient Indian sites. Kanungo (2002a, pp. 54–120, 2004b, 2004c) lists 204 sites which have yielded evidences of glass. Glass beads occur in about 150 sites and 36 are claimed to have been manufacturing sites (Kanungo, 2004a, p. 123).

The earliest evidence of glass beads (two well-made unweathered black and white tabular eye beads) in India is reported from Bhagwanpura in the Harappan-Painted Grey Ware overlap phase (period I), c. 1400–1000 BCE (Joshi, 1993). The occurrence of one glass bead in period II (Protohistoric) at Navdatoli shows that glass was not unknown to the people of this period (Deo, 1955, p. 10). The evidence of glass in the Chalcolithic period is very poor, found only at

Maski. During the next cultural phase of Indian history, i.e., Painted Grey Ware, we find that the occurrence of glass is quite common and widespread. It is found at several sites in India, which are widely separated from each other. Glass finds, although limited in number, have been a constant feature in all the levels from the sixth century BCE onwards. However, sites of Ochre Colored Pottery (OCP) culture have yielded only a few beads (Niharika, 1993).

The evidence of stratified eye beads from Northern Black Polished Ware (NBPW) phase, which form the next important stage in the study of glass in India, possibly supports the impression that mature glass came to India from the Mediterranean countries.

The technique of glass manufacture was well known since the seventh to sixth century BCE (Margabandhu, 1971, p. 1219, 1985, p. 327). Once the manufacturing processes were standardized, during the latter half of the first millennium BCE glass objects were produced on a mass scale. The very material and objects made of the glass found during this period bear an eloquent testimony to the fact that the making of glass in a furnace and later remaking and shaping them to beads had been fully understood and utilized to the maximum extent by the artisans of the times (Margabandhu, 1975, p. 73). The site of Kopia in Santh Kabir Nagar district (earlier part of district Basti), dated to about fifth century BCE, has yielded innumerable glass beads, thousands of glass fragments, fragments of clay crucibles with glass sticking to them, big pieces of glass and lumps of unworked glass (Abdurazakov, 1987, p. 38; Dikshit, 1969, p. 39; Lal, 1987, p. 45; Roy & Varshney, 1953; Sen & Chaudhuri, 1985, pp. 64–65). One large block of glass weighs about 76 kg and measures $45 \times 30 \times 22.5$ cm (Lal, 1987, p.45). Unfortunately, a few excavation reports of Indian sites yielding glass objects have discussed the manufacturing techniques involved and none the basis of the same (Kanungo 2000–2001, 2001, 2004a).

From 500 BCE onwards and particularly during the Maurya period, glass objects of all kinds came to be manufactured widely (Lad, 1983, p. 67). In Mauryan (fourth to second centuries

BCE) and Sunga (second to first centuries BCE) periods, beads of all kinds were plentiful including those made of glass (Alkazi, 1996, p. 7). The best evidence is that of glass seals from Maheshwar, Patna, Ujjain and three glass seals from the Mauryan phase at Taxila. The seals are mostly green and pale blue, carefully moulded and subjected to annealing to remove the internal strain. Spool (externally grooved) shaped ear-plugs, beads and bangles constitute the bulk of the glass articles known from specimens from Ahichchhatra, Kausambi, Patna and Rajghat.

The beginning of the Christian era witnessed the ushering of foreign cultural elements into Indian life. This is reflected not only in new shapes, but also in the introduction of new materials like the Mediterranean fine-grained corals and glass (Deo, 2000, p. 6). Use of glass became quite common. Findings at Arikamedu, Nevasa, Taxila and other sites present evidence for this. Excavations at Chandravalli, Karad, Kolhapur, Kondapur, Maski, and Nasik have each yielded valuable materials of high quality from the Satavahana period (first century BCE to early third century AD). Wound and drawn beads are often found (Deo, 2000, p. 27). Beads with white stripes are known to have come from Kolhapur, Kondapur, Maski, Nevasa, Prakash and Ter in the Deccan. These beads are common enough at Tripuri and Ujjain. By the dawn of the Christian era, the use of glass for beads became more popular. Many techniques were adopted for the manufacture of beads and ornaments during this period (Margabandhu, 1985, p. 203).

Abdurazakov (1987, p. 38) speaks of finding fragments of Middle Age glass at nine archaeological sites in India: Ahichchhatra, Arikamedu Assam, Jaipur, Kausambi, Kurukshetra, Nalanda, and Udaigiri. He mentions the evidence of glass and clay pots (used for glass production) at Dargai in Pakistan too.

By the time of Harsa (seventh century AD), glass was no longer a luxury as it must have been in the Satavahana period and was even used by mendicants and aboriginals (Agrawal, 1953, p. 186; Kanungo, 2002b). In Deccan, with the establishment of the Sultanates (twelfth to thirteenth century AD), the country witnessed the

rise of small-scale cottage industries for the fabrication of glass beads, as evidenced by the discoveries at Kolhapur and Nevasa in Maharashtra, and Maski in Karnataka and Sirpur in Madhya Pradesh (Deo, 2000, p. 6). The lacuna in our knowledge about the other contemporary Indian glass objects is almost certainly due to inadequate excavations of historical sites.

Chemical analysis of the specimens of about 18 areas shows that Indian workers were well acquainted with the raw materials and coloring agents used for the preparation of glass. In some of the specimens of Taxila glass, the presence of lead oxide and in some of the Tripuri specimens (200 BCE) the presence of barium oxide has been found. Presence of lead in glass gives rise to the formation of crystal glass and that of barium imparts to glass high resistance to heat.

In comparison with commonly occurring archaeological material such as pottery or metals, the glass in ancient sites occurs less frequently. Glass was never produced, on a very large scale, or over so wide an area as other materials. This is due to the fact that it required advanced technological skills to generate and maintain the required temperature for production of glass for long periods. This very often mirrors the general technological level of society. However, considering the spread of proto glass and its by-products in Protohistoric, its contemporary and later periods there is every possibility that glass might have developed independently in India. Glass seems to have appeared 500–1,000 years later than in Mesopotamia and Egypt.

In the Indian context, literary data and archaeological evidence point to the same time period for the occurrence of glass. Reference of *kāca* comes from the *Brahmana* group of texts which are assigned to the same time period as that of the Painted Grey Ware. Glass becomes more common in the Northern Black Polished Ware period. This is also reflected in literary data of the fourth to fifth century BCE, which abounds in references to glass.

In the early Christian era glass was not only found throughout the country but its by-products like beads were also produced using indigenous techniques. Subsequently, many places emerged

as production centers of a flourishing glass industry, as it had become by now an article of common use and was no longer a precious and rare commodity. Glass is more abundantly seen at the dawn of the Christian era.

No archaeological site except Nevasa has as yet given evidence of a glass furnace. This is probably

due to the fact that since production of glass requires a high temperature for a long time period, and in earlier days furnaces were generally made of clay, they collapsed or broke down at a fast rate. Thus in the archaeological context, not only does glass need to be classified and recorded, but the debitage also needs to be carefully collected and

Glass in India, Map 2 Evidence of glass and glass beads in Indian archaeology between 600 and 300 BCE. 1 Alagankulam, 2 Amethi, 3 Ayodhya, 4 Benagutti, 5 Champa, 6 Danwa, 7 Daulatpur, 8 Dharanikota, 9 Dhatva, 10 Ganwaria and Salargarh, 11 Gauriganj, 12 Harnol, 13 Hastinapur, 14 Hulas, 15 Jajmau, 16 Jakhera,

catalogued. (Debitage is the collective term used by archaeologists to refer to the sharp-edged waste material left over when someone creates a stone tool (knaps flint). Debitage is probably the oldest artifact-type recognized by archaeologists; the term is a French one but widely used by archaeologists the world over.)

The evidence of glass in Indian archaeology is spread in both time and space. Though there have been claims at regular intervals by different authors about the glass being introduced to India from outside, sometime in the Indo-Roman period, the evidence from as many as 29 sites gives ample evidence that glass was known

much earlier and could have been produced locally (Map 1). Besides, there is also stray evidence of glass in Bhagwanpura (Painted Grey Ware-Harappan overlapping), Dwarka

(late Harappan) and Maski (Chalcolithic), which are of much earlier cultures. Likewise there are 34 sites, which have evidence of glass beads in association with the Northern Black Polished

Ware period or in the period in between 600 and 300 BCE (Map 2). However, with the beginning of the early Historic phase, and more particularly in the early Christian centuries, the evidence of glass from as many as 119 sites suggests large-scale use (Map 3). This period is between 300 BCE and 400 AD and is characterized by red ware, red polished ware, russet coated painted ware, red and black slipped ware, black slipped ware and rouletted ware. All the same, during the Medieval Period there is clear indication that glass was becoming quite common as evidenced by its presence at 70 sites in the early Medieval period (400–1300 AD) (Map 4) and 49 sites in the late Medieval period (1300–1800 AD) (Map 5) (for details see Kanungo 2002a, 2004c). Considering such spread of glass and its by-products in ancient India, it is highly likely that around the early Christian era there should have been more regional major producers of glass other than the established site of Arikamedu in the south. In this regard Kopia in the north with its strategic location, abundance of glass, glass beads, crucibles and other debitage on the surface stands apart, and further work followed by a systematic excavation of this site could result in better understanding of ancient glass technology in India.

Glass in the Middle East

Stéphanie Boulogne

CNRS (Associated), IESA, Paris, France

Introduction

Glass, *zujāj*, in Arabic transcription, has been well known in the East since the third millennium (Mesopotamia). It is obtained by mixing a “forming” (silica, mainly found in sand) with a flux (natron) or plant ashes (soda, from *Salsola* soda or potassium ashes) and a stabilizer. Then, the substance is fired at at least 1,000° (Foy & Nenna, 2001; Marin, 1877–1919; Whitehouse, 2002).

Glass from Islamic times is generally found in very small quantities, especially compared to pottery. Fragments constituted of plain glass with a few decorated samples are usually blown or mold-blown; those could be of vessels, windows, bangles, beads, pins, or weights. The paste color as well as the quality, translucent or opaque, may be different regarding location and dating. The glass is most frequently blue, brown, or green but few samples of yellow, or white colors are also identified.

This entry will introduce Islamic glass from the seventh to the nineteenth century in the three main geo-cultural areas: Near East; Iraq, Iran, and Central Asia; and Arabia and Gulf areas. A last fourth will speak of the colored glass bangles known from the Mediterranean to Arabia.

The Near-East

The First Centuries

During the first centuries of the Islamic period (Omayyad: 661–750), the legacy of late Antiquity and Byzantium is really strong (Illustration 1). Glass fragments discovered in Bilad al-Sham as in Damascus and Bosra in Syria, Beirut in Lebanon, and Jerash in Jordan (Dussart, 2000, pp. 91–96) are close to those identified in the archaeological levels of Istabl ‘Antar-Fostat and Tebtunis in Egypt (Foy, 2000a, pp. 151–178). Those may be identified as balsamaria, flasks, and pitchers, and sometimes they are decorated with glass threads applied, pinched, or embossed (Dussart, 1998).

With the Abbasid Caliphate (751–1258) and the Tulunid dynasty in Egypt (808–965), one important novation was the invention of painted luster glass, sometimes attributed to Coptic workshops. It is obtained by putting copper and silver oxides on the surface of the glass object and firing it in an oxygen-free atmosphere. Many painted luster samples have been unearthed in Near Eastern archaeological sites, particularly at Fustat-Misir (Scanlon & Pinder-Wilson, 2001). Another kind of glass is millefiori which had been

discovered in Qasr al-Hayr al-Sharqi in North Syria (Grabar, Holod, Knustad, & Trousdale, 1978).

Monumental mosaics, *fusayfisa*, are a rich expression of glass, particularly in the Near East. The Dome of the Rock at Jerusalem and the Umayyad Mosque in Damascus (Kenney, 2006, pp. 175–200) are from the first centuries. Numerous glass weights or impressed tokens are stored in the museum collections (Launois, 1949).

Glass workshops were located at Tyre on the Mediterranean coast (al-Mas‘udi, al-Muqaddasi in the tenth century: Lamm, 1929, 1930, p. 491; Aldsworth, Haggarty, Jennings, & Whitehouse, 2002, pp. 49–66), Beirut, and Istabl ‘Antar-Fostat (Foy, 2000a).

Fatimid Caliphates (1069–1171) A huge quantity of glass – cups, dishes, jugs, beakers, and lamps commonly attributed to the Fatimid workshops – was discovered in the shipwreck of Serçe Limani in Turkey (Bass, Lledo, Matthews, & Brill, 2004). Beakers and flasks were also found in archaeological sites at Tebtunis and Istabl ‘Antar-Fostat in Egypt (Foy, 2000a, pp. 151–178; 2000b, pp. 239–290). Marvered glass is also assigned to this period. Colored tokens have also been discovered.

Crusader Times (1094–1187) In Akko, Jerusalem, fragments of plain glass were discovered. Some were decorated with prunts [a small mass of glass fused to the body of a glass piece] (beakers); others were marvered (Gorin-Rosen, 2013, pp. 109–116).

Ayyubid Times (1171–1250) This time is well known for the discovery of enameled and gilded glass fragments, unearthed in all the Ayyubid territories (including Bilad al-Sham), but more common in North Syria, Raqqa (Euphrate), Hama, and Mina in Turkey. Fragments are generally identified as beakers; other shapes could be long-necked bottles or flasks.

C. Lamm identified several typological groups of enameled and gilded glass (Blair & Bloom, 2009, pp. 114–115; Carboni, 2002;

Glass in the Middle East, Illustration 1 Animal flask (late seventh–eighth century). Yellow and pinkish, blown glass, applied decoration (Metropolitan Museum of New-York (USA); IAP artstore, Open Access for Scholarly Content (OASC), Met’s Website)

Carboni, & Whitehouse, 2002; Lamm, 1929, 1930). This technique had spread to Venice during the thirteenth century (Carboni, 1998, pp. 101–106; Whitehouse, 2014, pp. 73–78). The origin of the enameled ware could be Iran or Byzantium; the gild process is supposed to have been introduced from Anatolia and Seljuk (Abd el-Ra'uf al Yousuf, 1998: pp. 20–23; Genito, 1977, pp. 12–13). Some beakers are mentioned in medieval inventories and stored in international public collections.

We can also find some thread decoration applied around the long necks of some bottles and marvered decorations on the body of some fragments. Circular impressed weights of inscriptions are always known.

Workshops are well certified by the textual sources. In Syria, Aleppo particularly specialized in enameled glass (al-Qazwini, in the thirteenth century: Lamm, p. 491). In Raqqa, Rafiq, in North Syria, glass sherds have also been found, and other archaeological remains allowed us to conclude that there were glass workshops (Henderson, 1999, pp. 225–240).

Mamluk Times (Bahri (1250–1382) and Burji (1382–1516) Dynasties (Ill. 2 and 3)

Fustat, Quseir el-Qadim, in Egypt had revealed some glass fragments of Mamluk times (Whitcomb & Johnson, 1979, 1982), as have other sites in Bilad al-Sham, Khirbat Faris, Tell Abu Sarbut, and Tell Hesban in Jordan (Illustration 2).

These shapes could be quite different from the earlier ones. There are large dishes or vases and long-necked bottles. Enameled decoration is used as well as the gilded decoration. Mosque lamps illustrate a plain beautiful expression, with a particularly characteristic iconography of calligraphy, written generally in Thuluth.

However, this production is said to have been stopped during the fourteenth century, while Europe, especially Venice and Spain, began to produce those kinds of objects (Carboni, 2007; Whitehouse, 2014). Glass weights are well identified also, as previously.

Regarding glassmaking places, workshops at Hebron, Damascus, and Cairo are also mentioned

Glass in the Middle East, Illustration 2 Beaker with fish motifs (thirteenth–fourteenth century). Glass colorless with yellow tinge blown, applied ring foot enameled and gilded (Metropolitan Museum of New York (USA); IAP artstore, Open Access for Scholarly Content (OASC), Met's Website)

in the sources (Poggibonsi, Schmidt, al-'Umari in Lamm, pp. 492–493).

Ottoman Times (14th–19th) Workshops run by the State became the rule in Turkey, especially in Istanbul, and the guilds played an important role for art crafts. Manuscripts illustrations as in the *Surname-I Hümayun* (Guilds Procession, sixteenth century, stored in the Topkapi Palace Museum Library) display interesting iconography. European connections were strong; Ottoman sultans ordered mosque lamps from Venice (Carboni, 2007; Whitehouse, 2014).

Local provincial workshops continued their activity (Henein, 1974), even if the glass quality was poor. More glass was imported from the Empire, especially from Austria and Hungary. Beykoz glass was a new kind of glass that has

Glass in the Middle East, Illustration 3 Mosque lamp of Amir Qawsun 'Alib Ibn Muhammad al-Barmaki (1329–1335). Glass colorless with brown tinge, blown applied foot enameled and gilded (Metropolitan Museum of New-York (USA); IAP artstore, Open Access for Scholarly Content (OASC), Met's Website)

been manufactured around Istanbul since the nineteenth century (Kucukerman, 1998; Moraitou, 2013).

Iraq, Iran, and Central Asia (Ill 4 to 6)

Ninth to Thirteenth Century, from Abbasids to Seljuk (Ill. 4 and 5)

During the first centuries (Samanid dynasty, for example, from 819 to 999), as in the Near East, art glass production was strongly influenced by the late Iranian antiquity, particularly Sassanid glass production (Illustration 3).

At Samarra, in Iraq, at one time a capital (838–883) of the Abbasid caliphate (750–1258), an interesting glass corpus has been recorded: fragments of flasks, cups, lamps of undecorated blown glass, brown window glass, and decorated glass as millefiori (bowls and pavement floor), deep blue and scratched glass, threads glass

applied, and white glass with circles (relief-cut technique). Some shapes have been interpreted as having medicinal or alchemical uses (Lamm, 1928).

Objects from the Herzfeld excavations (Ernst Emil Herzfeld 1879–1948) are stored among several international museum collections such as the Metropolitan Museum of Art in New York, the Museum Fur Islamische Kunst in Berlin, and the British Museum.

Susa's glass corpus in Iran (Khuzestan), dated from the eighth to the tenth centuries, displays really interesting samples of vessels which are similar to those of Samarra, with some more "Persian" characteristics. Some are also interpreted as having medical or alchemical uses (Lamm, 1928, 1931); a collection is stored at the Louvre Museum in Paris. Another glass corpus was found during the Nishapur excavations, a site located in Khurasan, in Iran (dated from the ninth century to the first part of the thirteenth century); today this is mainly stored in the Metropolitan Museum in New York; it displays fragments of blown, mold-blown glass, with pinched or stamped decorations, glass threads applied, wheel-cut, millefiori, painted luster, or scratched patterns. Some shapes identified are lamps, windows, game pieces, or molar flasks (Kröger, 1995). Colored impressed glass tokens supporting a figurative iconography are known from Ghaznavids (977–1186) palace excavations in Afghanistan (Carboni, 2001).

Regarding glassmaking, a workshop seems to have been identified in Samarra (Northedge, 2005), and Kröger has proposed the possibility of a local one at Nishapur, even if there is no archaeological evidence of local manufacture. Around 17 furnaces have been identified at Sirjan and at Gurgan in Iran (Kröger, 1995).

Mongol Times: Ilkhanids (1256–1353) and Timurids (1370–1506)

Near Eastern art craft workers are frequently quoted as deported by Timur (Tamerlan) in Samarkand, Central Asia, and there are others citations of Near Eastern glass sent to the Golden Horde territory (Kramarovsky, 1998, pp. 20–23). There are also archaeological sources

Glass in the Middle East, Illustration 4 Blue glass fragment from Samarra (Herzfeld Collection, British Museum; Courtesy of the Trustees of the British Museum)

which testify to local production (Abdurazakov, 1972, pp. 161–178). Some long-necked mold-blown bottles with a decoration of mesh patterns are frequently attributed to the twelfth to thirteenth century (Museo Nazionale d'Arte Orientale, Giuseppe Tucci; Doha Museum: Walton, 2013).

Safavids (1501–1736) and Qadjar (1779–1924)

Long-necked bottles as sprinkle containers for rosewater are frequent in the museum collections. During the seventeenth century, textual sources such as Tavernier and Lemans mentioned glass workshops at Isfahan and Shiraz which produced bottles of different colors (Lamm, pp. 500).

Arabia and Gulf Areas (III.7)

Glass finds have been unearthed during excavations of coastal sites at Sharma, al-Shihr (Foy, in process; Boulogne, & Hardy-Guilbert, 2010, pp. 135–148) (Illustration 4). Others have been found in the south of the Arabian Peninsula, around Aden and Julfar in the Persian Gulf (Hansmann, 1985, pp. 76–83; Boulogne & Carter in process) and also in Bahrain (Lombard & al-Sindi, 2013) and in Kuwait. There have also been fragments found in Saudi Arabia, at Masafi, and Yamama (Benoist, CNRS; Schiettecatte CNRS).

Glass in the Middle East, Illustration 5 Green Glass fragment decorated with a star motif, Samarra (Iraq), probably south thronehalls (Herzfeld Collection, British Museum; Courtesy of the Trustees of the British Museum)

Glass in the Middle East, Illustration 6 Yellow green Glass bottom Bottle, Samarra (Iraq), private houses (Sketched by Herzfeld in his Sketchbook 4, p.11 (Herzfeld's Finds Journal); Courtesy of the Trustees of the British Museum)

Finds of the first levels generally display Abbasid styles or shapes, as, for example, little cosmetic containers of fusiform shape (tapered at both ends) and thick deep blue glass or white with embossed patterns of circles. Glass is also recorded among the finds excavated from the

Glass in the Middle East, Illustration 7 Green glass fragment (attributed to Omeyyad times). Discovered at Khadima archaeological site (Kuwait) (D. Kennet excavations at Khadima; Courtesy of D. Kennet)

Glass in the Middle East, Illustration 8 Green glass fragment bangle decorated with yellow prunts (attributed to Samarra, Iraq) (Courtesy of the Trustees of the British Museum)

Glass in the Middle East, Illustration 9 Al-

Yamama glass corpus, al-Yamama (Riyadh, Arabia Saoudi) (Courtesy by Jérémie Schiettecatte CNRS – UMR 8167 “Orient et Méditerranée”)

medieval and later levels; generally those are fragments of thin little or medium concaves back bottles of green glass. Textual sources, particularly of the thirteenth century, talk about some gilded glass imported from the Near East to Yemen; at the same time, others mentioned workshop locations around the area of Aden (Boulogne & Hardy-Guilbert, 2010). Bahrain in the Persian Gulf must certainly have also had workshops.

A Phenomenon from the Near-East to Arabia: Colored Glass Bangles (Ill.8 to 11)

Well known during Antiquity (Spaer, 2001), in monochrome only, bangles dated from Islamic times are both monochrome and polychrome. They have interesting technical and varied chromatic decorations. Some were found in the first levels (Umayyad and Abbasid) of Near Eastern archaeological sites (as Khirbat Minyeh) and some in Qasr al-Hayr al-Sharqi (north of Syria) and Samarra (Iraq) (Grabar, 1978). Most come from medieval and late Islamic levels at sites located in the Near East, the Arabian Peninsula, the Persian Gulf, and sub-Saharan Africa. They also appear in Europe, particularly in Spain (Monod, 1975, pp. 702–718). Amazingly, there are very few from Iranian archaeological

Glass in the Middle East, Illustration 10 Glass bangles (fourteenth–fifteenth centuries), Near-East (Courtesy by J. Schiattecatte, CNRS)

Glass in the Middle East, Illustration 11 Glass bangle (fourteenth–fifteenth centuries), Near-East (Metropolitan Museum of New-York (USA); IAP artstore, Open Access for Scholarly Content (OASC), Met's Website)

finds except from South Balochistan. Glass bangles found in Islamic lands are totally different from Byzantine glass bracelets, and until now, we could identify at least two main different groups: Near Eastern and Arabian (with an Indian influence for some). Both groups demonstrate the same stylistic vocabulary combined with a

singular type of colors and variation around the size and profile. Techniques observed on Islamic glass bangles can be compared to this use in glass vessels (enameled, marvering, prunts), and patterns to this of some precious silver bracelets attributed to the Seljuk (Iran) and the Fatimid (Near East) (Hasson, 1987).

A bangle workshop was identified in the city of Hebron (fourteenth to fifteenth century) in the Near East, and Kröger mentioned a glass workshop in Dvin (Armenia), where a lot of bangles dated of the 10th–13th levels have been excavated. Could there have been bangle manufacture in Dvin? (Illustrations 7–10)

Acknowledgement I warmly thank Mr. Derek Kennet (archaeologist, lecturer Durham, UK), Mrs. Venitia Porter (head of Islamic art and archaeology Department at British Museum London, UK), and Mrs. Rosaleen Haddon (archaeologist, head of the Samarra find inventory at the British Museum, London, UK) for their help. I really thank very sincerely Mrs. Helaine Selin, editor of *Encyclopaedia of the History of Science, Technology, and Medicine in Non-Western Cultures* for her very strong and fortunate help in the translation of this article. Finally, I am really grateful to **Michael Jung (curator at Museo Nazionale d'Arte Orientale, Roma)** for the precious references he has provided me and I thank you very much J. Schiattcate for his interest and support.

Glazes in China

Weidong Li

Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China
 Key Scientific Research Base of Ancient Ceramics, State Administration for Cultural Heritage, Shanghai, China

Introduction to Chinese High-Fired Glazes and Low-Fired Glazes

Glaze is a vitreous coating of glass that has been fused to a body through firing; it can color, decorate, strengthen, or waterproof the coated body. Ancient Chinese glaze is both a beautiful and mysterious science that includes high-fired glaze and low-fired glaze. High-fired glaze is applied to

Glazes in China,

Fig. 1 Phase diagram of $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-CaO}$ ternary system (Rawson, 1967)

porcelain or stoneware, whereas low-fired glaze is applied to pottery. Traditional Chinese high-fired glaze falls into the category of calcium glaze, calcium-alkali glaze, or alkali-calcium glaze, which originated from the plant ash glaze from the Shang dynasty (1700–1027 BC) (Li, 1998). Adding calcined plant ash and limestone was advantageous for the vitrification of glaze; the addition serves as a flux, enhances the glaze's stability, minimizes glaze defects, and modifies the fit and bonding between the glaze and body. Chinese low-fired glaze is either lead glaze or lead-barium glaze and originated in the Warring States Period (475–221 BC). Its origin is closely linked with the Chinese lead-barium glass which was invented in the Western Zhou dynasty (1027–771 BC). However, the most famous of the low-fired glazed pottery is the tricolored glazed pottery of the Tang dynasty (618–907 AD). Due to the toxicity of lead, it usually serves as a burial object in tombs.

Physicochemical Basis for High-Fired Glazes

The high-fired glaze category can be divided into two groups: transparent glaze and opaque glaze. Transparent glaze is a homogeneous vitreous

glaze, whereas the opaque glaze contains light scatterers within the glaze, such as microcrystals or phase-separation structures or both. The high-fired glaze has the following principal constituents: SiO_2 , Al_2O_3 , CaO , MgO , K_2O , and Fe_2O_3 , which can be roughly represented with the $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-CaO}$ ternary system by merging MgO and Fe_2O_3 into CaO and ignoring K_2O . The physicochemical basis of Chinese high-fired glazes can be supposed within the confines of the phase equilibrium relationships of the $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ system and the metastable liquid-liquid immiscibility region above 950 °C (Rawson, 1967) (Fig. 1).

Phase-Separated Glaze

If the glaze composition falls into the liquid-liquid phase-separation region above 950 °C (Fig. 1), the physical chemistry is adequate for phase separation. Phase separation in glazes is primarily determined by the strong immiscibility tendency between SiO_2 and CaO (Mazurin & Porai-Koshits, 1984).

A celadon glaze from the Qionglai kiln is a high-fired opaque glaze with mild gloss. One thing that can distinguish the glaze from others

Glazes in China, Fig. 2 An opaque celadon glaze from the Qionglai kiln. (a) SEM image, showing submicron droplet phase-separated structure, (b) visual effect of the glaze

G

is its extraordinarily high calcia (14.89–19.46 wt % CaO) and magnesia contents (4.24–6.88 wt % MgO). As shown in Fig. 2a, evenly dispersed submicron droplets which are separated out from the matrix serve as the light scatterers, with some of the droplets joining with each other. The droplet or joined droplet size ranges from 0.2 to 0.5 μm , which causes an intensive light scattering and thus results in good opacification (Li, Wu, Li, & Guo, 2002). In this case, chemical coloring effect is dominant, and the submicron phase-separation structure is responsible for the glaze opacification. Figure 3 shows various visual effects of the phase-separated glazes from the Qionglai kiln, Song dynasty (960–1279 AD). Another example of phase-separated glaze is the mild blue glazes from the Jun kiln (Fig. 4), Northern Song dynasty (960–1127 AD).

Crystalline Phase-Separated Glaze

If the glaze composition falls into the primary crystalline phase region of anorthite (Fig. 1), it is limited to the un-equilibrium thermodynamic conditions during the firing process, and consequently, anorthite is the only crystal precipitated from the molten glaze. With anorthite growth, the alumina of the residual glass is heavily consumed; it is then followed by a rapid composition shift as the $\text{SiO}_2/\text{Al}_2\text{O}_3$ ratio rises dramatically

and enters the metastable liquid-liquid immiscibility region above 950 °C.

Within the interspaces of the anorthite clusters or around the brims of the anorthite needles or columns, a rough texture characteristic of the nano-sized liquid-liquid phase separation can always be observed. It results from the local chemical variation of the residual glass caused by anorthite crystallization (Li, Li, Deng, Wu, & Guo, 2005; Li, Luo, & Li, 2009) (Figs. 5, 6, and 7). The formation process of phase separation is complicated as it is influenced by the chemical composition variations, the viscosity-temperature relationship of melt, and the firing conditions, such as the temperature and atmosphere. As such, a great deal of variations can be expected. These anorthite crystals pack in different densities and cause varying chemical heterogeneity and, consequently, resulting in various scale phase separations. Opaque green glazes from the Yaozhou kiln (Five Dynasties, 907–960 AD), Ru kiln (Northern Song, 960–1127 AD), Zhang Gong Xiang kiln (Northern Song, 960–1127 AD), and Southern Song imperial kiln (1127–1279 AD) are typical of crystalline phase-separated glazes.

High-Iron Glaze

Through its array of complex yet subtle functions, iron is the most impressive element in

Glazes in China, Fig. 3 Visual effects of the phase-separated glazes from the Qionglai kiln, Song dynasty

Glazes in China, Fig. 4 Visual effects of the phase-separated glazes from the Jun kiln, Northern Song dynasty

G

ancient Chinese glaze. It acts as both a flux and a coloring element; it favors the strong immiscibility tendency between SiO_2 and CaO and will precipitate from the glaze under supersaturation. Using the famous Jian kiln ware as an example, Fe is critical for producing the fantastic exterior appearance of the tea bowls from the Song dynasty (960–1279 AD) from the Jian kiln. If Fe

is ignored, the Jian glaze concentrates in the primary crystalline phase region of anorthite. However, in reality, the case is not that simple since the 4–7 wt% iron oxide in the glaze would not be ignored. With glaze composition variation, the microstructure formation would probably result in three distinct possibilities (Li, Luo, Li, Li, & Guo, 2008): (1) precipitation of anorthite

Glazes in China, Fig. 6 An opaque green glaze from the Ru kiln, Northern Song dynasty. (a) SEM image, showing interconnected phase separation around the brims of anorthite crystals, (b) visual effect of the glaze

Glazes in China, Fig. 7 An opaque green glaze from the Lao Hu Dong imperial kiln, Southern Song dynasty. (a) SEM image, showing various scale interconnected phase-separation structures, (b) visual effect of the glaze

accompanied by an intercrystal phase separation and the subsequent precipitation of iron oxide, (2) precipitation of iron oxide favored by phase separation, and (3) formation of homogeneous amorphous black glaze. Furthermore, the glaze microstructure is highly related to the composition and firing schedule. Figures 8, 9, 10, 11, 12, and 13 detail the typical microstructures and visual effects of the high-iron glazes from the Jian kiln.

Transparent Vitreous Glaze

If the glaze composition falls into the primary crystalline phase region of tridymite and with

mole ratio of $\text{Al}_2\text{O}_3:\text{SiO}_2$ between 1:11.5 and 1:7 (Fig. 1), limited to the unequilibrium thermodynamic conditions during the firing process, no crystal will precipitate, and thus, a transparent vitreous glaze is formed. An interaction layer consisting of a dense anorthite microcrystal growth reaching into the glaze usually forms at the glaze-body interface due to the diffusion of aluminum ions from the body into the glaze (Li, Luo, Sun, Liu, & Zhao, 2011) (Fig. 14). At this interaction layer, an anorthite-accompanied phase-separation structure can always be observed. Many Chinese ancient kiln sites produced transparent-glazed wares, such as the Yue kiln, Yaozhou kiln, Xing kiln, Ding kiln, Gongyi kiln, Longquan kiln, Dehua kiln, etc.

Color and Texture of Ancient Chinese Glaze

A glaze's color and texture are determined by its chemical composition and microstructure. Glaze texture is characterized by its transparency and gloss, which is directly related to the amount, size, and distribution of the scatterers (bubble, crystal, and liquid-liquid immiscible structure) that are existing in the glaze as well as at its surface. Factors affecting the glaze color include the chemical factor (a coloring agent such as iron ion chromophore) and the physical factor (structural coloring); which factor is predominant depends upon specific cases.

The origin of Chinese porcelain is celadon, which is suitable for the Chinese people's

implicit and humble character as well as guides their special aesthetic taste. The restrained, preferential monochromatic effects imitated or harmonized with the colors of nature, such as the tree, plant, jade, water, and sky. Green glazes in particular have a complicated coloring mechanism and diverse colors.

For the transparent celadon glaze, the transition metal iron ion is the principal coloring constituent. In fact, there is no doubt that the $\text{Fe}^{2+}/\text{Fe}^{3+}$ ions determine the glaze color; furthermore, the body's color beneath the transparent glaze also modifies the visual effect of the glaze color. The light energy absorption mechanism, and thus the production of chemico-compositional coloring, can be explained by an electron displacement or excitation in the absorbing material. Thus, part of the

Glazes in China, Fig. 13 An oil spot glaze from the Jian kiln, Song dynasty. (a, b) OM images of oil spots, showing iron oxide crystals precipitated on *top* of the glaze surface, (b) visual effect of the glaze

Glazes in China, Fig. 14 SEM image of the cross section of a white porcelain pot from the Gongyi kiln, Tang dynasty. (a) Transparent glaze and an interaction layer at glaze-body interface, (b) close-up of (a)

energy in the incident radiation is utilized in producing excitation, and the light of certain wavelengths falls upon the surface and tends to be reflected selectively. Furthermore, the iron ions' oxidation state or the combination or coordination mode is highly significant. In the glaze, there is a reduction-oxidation equilibrium for Fe^{2+} and Fe^{3+} that is determined by the glaze melt status determined by temperature and kiln atmosphere. Consequently, the ratio of ferrous to ferric iron has an important bearing on the exhibited color, which could be measured using a XANES spectra or Mössbauer spectra.

The coloring mechanism underlying the opaque and translucent glaze is more complicated. Using the Ru glaze as an example, a dual coloring mechanism is in effect by covering the chemico-compositional coloring by the iron ion chromophore and the structural coloring caused by structural inhomogeneities of the nanosized phase-separation structure. As the following scatterers are in the submicron and micron size range, various bubbles, residual quartz grains, undissolved batch material, and anorthite microcrystals create a full-waveband reflection and refraction upon the incident light and are, therefore, responsible for the opacification of the glaze layer. In this case, the size of the scattering particles exceeds the wavelength of visible light, and the Mie scattering theory applies.

Our latest research shows that the mild blue colors of the Ru glaze and Jun glaze primarily occur due to the phase-separation structure in the glazes, which is an amorphous photonic structure with short-range order. Photonic pseudogap results in selective reflection or a scattering of light in the visible range. The physical origin of this mild blue color is the coherent scattering effect resulting from the amorphous photonic structure. Furthermore, the structural blue color is both mild and angle independent. Additionally, computationally simulating the glaze's structure as well as simulating calculations of the optical properties has been conducted in order to establish the corresponding relationship between the structure and reflective spectrum.

Glazes in China, Fig. 15 A triangle representing correlations among the composition, microstructure, color, and texture of ancient Chinese glazes

Although glazes may come from the same kiln site, the glazes' coloring mechanism may still have some variability. This variability may be induced by firing glazes of the same compositions at different temperature schedules or a different kiln atmosphere; doing so may induce different microstructures. Furthermore, the temperature or kiln atmosphere varies in different firing processes or at different positions in the same kiln. Moreover, the Ru glaze colors are determined by both the chemico-compositional coloring and the structural coloring, and they are quite sensitive to the firing conditions. For example, Ru glazes of the same compositions may appear to be different colors, such as azure blue, sky blue, bean green, grayish green, or moon white. Both ion coloring and the phase-separation structure will affect the glaze color, whereas the micron-sized anorthite crystals in the glaze just result in glaze opacification (Fig. 15). The interaction and coordinated effect between the chemico-compositional coloring and structural coloring need to be further investigated.

In general, the chemical composition and firing schedule determine a glaze's microstructure, and likewise, both the composition and microstructure influence the glaze color and texture. Revealing the correlation among the compositions, the microstructures, the colors, and the textures of ancient Chinese glazes is of great importance.

Acknowledgments This work was supported by key project of Natural Science Foundation of China (No. 51232008) and National Basic Research Program of China (973 Program) (No. 2012CB720901). The author would like to thank Fujian Museum, Henan Provincial Institute of Cultural Relics and Archaeology, and Chengdu Municipal Institute of Cultural Relics and Archaeology for providing ancient porcelain samples for scientific research.

Globes

Emilie Savage-Smith

The celestial globe is the oldest form of celestial mapping, for its origins can be traced to Greece in the sixth century BCE. The stars were perceived as though attached to the inside of a hollow sphere enclosing and rotating about the earth.

The earth, known from early classical antiquity to be spherical, was imagined at the center of the globe, while the stars were placed on its surface. Since this three-dimensional model of the skies presented the stars as seen by an observer outside the sphere of stars, the relative positions of the stars on a celestial globe are the reverse, east to west (or right to left), of their appearance when viewed from the surface of the earth. The sequence of the zodiacal constellations will be counterclockwise when the globe is viewed from above the north pole.

No celestial globes from antiquity have survived, but the basic principles of their design were maintained, with some modifications and elaborations, in the Islamic world, where the earliest preserved celestial globes were made. By the ninth century celestial globes were being made in the Arabic-speaking world. The most important early Islamic center of globe-making was the city of Harran, between the northern reaches of the Euphrates and Tigris rivers. In the ninth and tenth centuries it was an important town at the intersection of major caravan routes and had a prominent Sabian community whose pagan religious interest in the stars and sun was perhaps conducive to the study of astronomy. Many of the early astronomical instrument-makers were members of the Sabian sect at Harran. Several Arabic treatises were composed in the ninth century on the design and use of celestial globes, including one by the famous astronomer of Harran, ► [al-Battānī](#) who was known in the Latin world as Albategni, and others by ► [Ḥabash al-Ḥāsib](#) and ► [Qusṭā ibn Lūqā](#) in Baghdad. In the following centuries, additional treatises on the subject were composed, including one by ‘Abd al-Raḥmān ibn ‘Umar ► [al-Ṣūfī](#) (d. 983) whose treatise on constellations became the model for constellation iconography in the Islamic world.

Over 180 Islamic celestial globes are known to be preserved today. The earliest was made in AD 1080 in Valencia, Spain, and the most recent in Ottoman Turkey in 1882. Regardless of date, the stars represented on Islamic globes are those listed in the medieval star catalogs, and only the 48 constellation outlines recognized in antiquity are indicated. When constellation outlines are drawn

around the stars, the clothing and faces of the human figures, such as Orion or Virgo, reflect the artistic conventions common in the artisan's day. Since the positions of the stars change over time with the precession of the equinoxes, the star positions on a globe, correct when the globe was made, remain valid for only three-quarters of a century.

In addition to the celestial equator and the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course), the Tropic of Cancer and the Tropic of Capricorn were also frequently shown on Islamic globes, as well as the north and south equatorial polar circles. On some later globes the ecliptic equivalents of tropic and polar circles were indicated, apparently in an attempt to complete the symmetry. On every Islamic globe preserved today there is also a set of six great circles at right angles to the ecliptic – six ecliptic latitude-measuring circles, reflecting the common use of ecliptic-based coordinates for measuring star positions. To function as an instrument, the sphere needed to be placed in a ring assembly, allowing for adjustment to a particular location. If supplemented by a gnomon or quadrant providing the altitude of the sun, the globe could then be used by an astronomer or astrologer to determine a range of astronomical data, including the length of the unequal day-time hour for a given day and location, or the time elapsed on a certain day, or data for a horoscope. It is questionable, however, whether many of the globes preserved today were of more than didactic or artistic value.

In terms of design, Islamic celestial globes fall into several distinct categories. The first includes the largest and the most elaborate artifacts, all of which display the 48 constellation outlines and approximately 1,022 stars. Those in the second category do not have constellation outlines. Only a selection of the most prominent stars, usually between 20 and 60, are shown.

The third type of design is one in which the globe has neither constellation outlines nor any stars. In general these globes are the smallest. They have on them only the great and lesser circles (ecliptic, equator, tropic, and polar circles), all of which are labeled. This design is not mentioned in any of the written sources, and evidence so far

available suggests it originated in Iran in the late seventeenth or early eighteenth century.

Only a few painted wood or papiermâché Islamic globes have survived, all of them hand drawn or painted. The method that dominated globe making in Europe – namely, laying printed paper gores over a wood or fiber core – seems not to have been practiced in the Islamic world. The vast majority of Islamic globes are hollow metal spheres and were made in two ways: from two hemispheres of cast or raised metal, or cast in one piece by the lost wax process. While globes made of wood or papiermâché or with metal hemispheres are of considerable antiquity, seamless globes, on the basis of evidence so far available, appear to have originated in northwestern India toward the end of the sixteenth century, the earliest confirmed date for one being AD 1589–1590. They became the hallmark of all workshops in the Punjab and Kashmir areas of India through the nineteenth century. The workshop that excelled in this technique was a four-generation family of instrument makers in Lahore (in modern Pakistan). During more than a century, this remarkable workshop produced numerous astronomical instruments, including 21 signed globes (the earliest made in AD 1622). The technique of making seamless globes continued to be practiced in India after this workshop ceased to make them.

Throughout the ten centuries of their production in the Islamic world, celestial globes maintained the medieval tradition of displaying only the classical constellations and stars. On metal globes the stars were usually indicated by inlaid silver points. None of the surviving Islamic celestial globes records the stars and constellations of the southern hemisphere first mapped by Europeans during explorations of the sixteenth century.

While the production of celestial globes was widely and continuously practiced in the Islamic world, there was no comparable tradition of terrestrial globe making. There seems to have been little interest in terrestrial globes until the sixteenth century, when early modern European terrestrial globes became known to Ottoman Turkish astronomers and in the next century to those at the Mughal Indian court.

► [Varāhamihira](#) gave a fairly complete account of its use in India in the *Pañcasiddhāntikā*. This was written in AD 505 and summarized the astronomical information current in India at that time. The *Āryabhaṭīya* of ► [Āryabhaṭa](#) also provides the main results of the theory of the gnomon, and these features appear again in the works of Bhāskara, ► [Brahmagupta](#), and many later astronomers.

The Cardinal Directions

The procedure is illustrated in Fig. 1. G is the foot of the gnomon. The path of the end of the shadow enters and leaves a circle, center G, at W and E. Then the line EW is in the east-west direction. With E, W as centers, circular arcs are drawn intersecting at N, S. Then NS, the perpendicular bisector of EW, is in the north-south direction and intersects the circle at N and S, the north and south points. The ► [east and west](#) points, E and W, can be found by the same procedure since they are on the perpendicular bisector of NS.

This method depends on the symmetry of the shadow path about the north-south line. It does not take into account the small change in the declination of the sun during the day.

Gnomon in India, Fig. 1 Finding the cardinal direction (Neugebauer, 1971)

Gnomon in India

George Abraham

The gnomon is an instrument used widely in early astronomy. The shadow of a vertical rod on a horizontal plane determines the cardinal directions, the latitude of the place of observation, the celestial coordinates of the sun, and the time of the observation.

Brahmagupta prescribed a correction for this error in the *Brahmasphuṭa Siddhānta*. This method of finding the cardinal directions, described in the *Pañcasiddhāntikā*, is found in a much earlier treatise, the *Śulbasūtra*, which contains mathematical topics related to the construction of sacrificial altars. The *Pañcasiddhāntikā* also has an approximate method for finding the meridian direction from any three positions of the shadow. This method assumes that the path of the shadow is a circle, whereas in India, it is a hyperbola.

The Noon Shadow

Trigonometric formulas enable us to find the latitude of the observer and the sun's declination from the shadow of the gnomon at noon, when the sun is on the local meridian. In Fig. 2, g is the height of the gnomon, s the length of the shadow, Z the zenith, S the sun, and z the zenith distance of the sun. On any day, the zenith distance at noon is $z = \phi \pm \delta$, where ϕ is the observer's latitude and δ the declination of the sun. The Indian formula is

$$\sin z = \frac{R_s}{\sqrt{s^2 + g^2}},$$

where the sine of an angle is defined as R times the modern sine function, R being a constant

Gnomon in India, Fig. 2 The noon shadow

angle, taken to be 120 min in the *Pañcasiddhāntikā*. When the sun is on the equator, $\delta = 0$, and the formula above gives us the latitude in terms of the length of the noon shadow. On other days, the formula yields the change $\pm\delta$, in the zenith distance, as a function of the noon shadow. On the days of the solstices, the declination has the maximum value, ε , the obliquity of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course).

When the sun is on the prime vertical (the great circle on the celestial sphere through the east and west points and the zenith), let z_1 be the zenith distance, and $\alpha_1 = 90 - z_1$, the altitude of the sun, and λ , the longitude of the sun. Then the *Pañcasiddhāntikā* formulae are

$$\sin \alpha_1 = \frac{R \sin \delta}{\sin \phi} = \frac{\sin \lambda \sin \varepsilon}{\sin \phi}.$$

With these two formulae, we can find the declination and longitude of the sun from the shadow length, when the sun is on the prime vertical.

With the gnomon, it was also possible to find the time after sunrise, from the length of the shadow, using formulae which are equivalent to those used in modern spherical astronomy.

The second formula above gives the sun's longitude λ and declination δ , when it is on the prime vertical. λ and δ can be determined at any time, from the length of the gnomon's shadow and the distance of its endpoint from the east-west line. The *Pañcasiddhāntikā* also gives an approximate empirical algebraic formula which would have been useful in very early astronomy:

$$\frac{d}{2t} = \frac{s - s_0}{g} + 1.$$

This gives t , the time after sunrise in the morning or the time before sunset in the afternoon, s_0 is the noon shadow, and d the length of daylight. This formula is derived from the following considerations:

1. There is a linear relation between s and $1/t$
2. At noon $2t = d$
3. $s - s_0 = g$ at $4t = d$

Gnomon in India, Fig. 3 Determining the altitude of the moon or planets

The *Yavanajātaka* of ► [Sphuḥjīdhvaja](#) also has this formula. Chapter 20 of Kauṭilya's *Arthaśāstra* gives the relation between the time after sunrise and the gnomon shadow. The *Arthaśāstra* also gives the rule for the uniform variation of the noon shadow from zero at the summer solstice to g , the gnomon height, at the winter solstice, a reasonable approximation for an observer on or near the Tropic of Cancer, for example at Ujjain. However, the rule for the uniform variation of the length of daylight from 12 to 18 *muhurtas*, also found in the two books above, implies a latitude of about 35° , which suggests a Babylonian origin.

The theory of the gnomon presented above can be applied to the moon and planets also. The altitude of the moon or planet is determined in the following manner, illustrated in Fig. 3.

The moon or planet (P) is seen reflected in a mirror M in the same horizontal plane as the foot G of the gnomon of height g at a distance d from the gnomon. Then the altitude a is given by the formula

$$\sin a = \frac{R_g}{\sqrt{g^2 + d^2}},$$

d is called the *reversed shadow* and takes the place of the shadow length s in the case of the sun.

The eleventh-century Arabic scholar ► [al-Bīrūnī](#) wrote *Kitāb fī ifrād al-maqāl fī umr al-ẓilā* (The Exhaustive Treatise on Shadows),

which contains a comprehensive account of the theory and applications of the gnomon shadow. Al-Bīrūnī refers to many Indian sources, for example:

1. The method described above for finding the cardinal directions. He calls it the method of “the Indian circle.”
2. The algebraic formula.
3. The time from the shadow. Al-Bīrūnī follows the procedure of ► [Brahmagupta](#).
4. Al-Bīrūnī gives the approximate Indian method for determining the meridian from three positions of the shadow. In addition, he describes the procedure, for the same problem, given by Diodorus of Alexandria, a mathematician of the first century BCE. An important result in al-Bīrūnī's book, not mentioned in his Indian sources, is the condition for the shadow path to be a parabola, ellipse, or hyperbola, depending on the latitude of the observer and the declination of the sun.

Gold in the Andes

Mark Aldenderfer
University of California, Merced, CA, USA

For almost 4,000 years, gold was held in high esteem by many societies that populated the Andes, and indeed, gold continues to be extracted in mines across the region.

Gold has a number of important properties that have made it attractive to cultures all over the world. It is both malleable (can be easily shaped by hammering) and ductile (it can be hammered into very thin forms and is thus highly flexible and not brittle). It can be used to form alloys with other metals such as copper and silver and in so doing add bright color to the finished product, and it resists corrosion and is unaffected by moisture or air. But perhaps most importantly, its golden-red color is attractive to the eye. It reflects sunlight easily, and when polished, it is quite brilliant. Given its relative rarity and the ease with which it can be worked, gold has long served as a

Gold in the Andes, Table 1 Period names, time frames, and archaeological cultures described in the text

Period name	Time frame	Site or archaeological culture
Late Horizon	1476–1534 CE	Inca
Late Intermediate	1000–1476 CE	Chimu
Middle Horizon	600–1000 CE	Wari, Tiwanaku
Early Intermediate	0–600 CE	Moche
Early Horizon	900 BCE–0 CE	Chavin, Kuntur Wasi
Initial Period	1800/1500–900 BCE	Waywaka, Mina Perdida
Archaic	ca. 2000 BCE	Jiskairumoko

desired and sought after commodity no matter what shapes it has taken. Simply put, gold signals prestige, status, wealth, and social power but to varying degrees depending on the culture in which it is found. As Quilter (2011, p. 45) notes, the value of gold is a social construct, and the value it takes depends greatly on that context.

The use of gold is part of an Andean tradition of metallurgy that begins deep in prehistory in the Archaic period (Table 1). As described by Heather Lechtman (2014, p. 369), three metals – gold, silver, and copper – form the basis of this tradition, and through time, larger, more complex artifacts and expanded technologies to fabricate them were developed. Beginning with simple cold hammering, metal-working technologies included annealing (exposing metals to fire to soften them for further work), soldering (the use of a metallic alloy to join metals), sweat welding (a version of soldering), smelting (the heating of ore beyond its melting point to obtain the metal in it), sintering (the fusing of small bits of metal below the melting point), and casting, including the lost wax method (liquid metal is poured into a mold to shape it). A wide range of ancillary techniques were used, including cutting, repoussé (hammering or molding a metal from the reverse side), chasing (refining a surface of an artifact from its front), burnishing, and pickling.

Gold in the Andes, Fig. 1 The gold necklace from Jiskairumoko. The beads have been restrung (Photo credit: Mark Aldenderfer)

Evidence for the earliest use of gold in the Andean world is found at Jiskairumoko, a site located in the Rio Ilave drainage in the south-western Lake Titicaca basin (Aldenderfer et al., 2008). The context in which the gold was found has been dated to 2204–1941 cal BCE, making it not only the oldest gold discovered to date in the Andes but also in the Americas.

Nine gold beads were discovered in a mortuary context of mixed adult and juvenile human remains. The adult was elderly, while the juvenile was from 4 to 6 years of age. The beads were found near the base of the adult cranium in a roughly circular pattern, suggesting they had been once formed into a necklace (Fig. 1). Eleven round, disk-shaped sodalite beads were also recovered in and among the gold beads.

The gold beads were formed by cold hammering and flattening quartz-vein native gold nuggets; the flattened metal was then shaped into a cylinder (Fig. 2). One of the beads was perforated and a small sodalite bead was found in the matrix near this bead, suggesting it was placed in this

Gold in the Andes, Fig. 2 One of gold beads from Jiskairumoko illustrating the folding of the bead and its perforation (Photo credit: Mark Aldenderfer)

hole. There is no evidence of heat treatment or annealing of the metal.

Aside from the early date, what is important about the gold from Jiskairumoko is the kind of society of which it was a part. The inhabitants of the site were mobile hunters and gatherers with an egalitarian social structure on the cusp of a profound social transformation that would eventually lead to greater social and political complexity. Used in a necklace, the gold served to signal the prestige of its wearer, while its interment with the deceased signaled the implied wealth and prestige of its owner and their kin.

Gold artifacts next appear further to the north at two Initial Period sites: Waywaka in the central highlands of Andahuaylas, dated to 1500–1000 BCE (Grossman, 1972), and Mina Perdida in the Lurin Valley, dated to 1400–1100 BCE (Burger & Gordon, 1988). This period is characterized by a significant increase in social complexity and political integration. Sites are larger, residence at them is permanent, and based upon the use of domesticated plants and animals, and in some instances, ceremonial structures are constructed. New technologies of gold fabrication also appear. At both sites, small, very thin fragments of gold foils were recovered. At Waywaka, the gold was hammered into small shapes and placed, like at

Jiskairumoko, in a mortuary context. In contrast, the gold at Mina Perdida was combined with small, thin sheets of copper and was used as a foil to cover it. The metal foils were found atop and near the pyramidal summit of a large mound constructed of soil and faced with stone. The presence of other artifacts reflecting supernatural iconography suggests that these metal fragments were part of a more complex artifact used in these ceremonies atop the mound.

Although forms of gold have changed, the technology to produce the foils continues the earlier tradition of cold hammering. Grossman (1972) found a number of stone bowls and pestles at Waywaka that are thought to have been used to pound native gold nuggets (see also http://www.geospatialarchaeology.com/album-Peru_large21.html for images of these artifacts and the context of their discovery).

In the following Early Horizon, the production of elaborate golden objects can be attributed to the expansion of the Chavin religious cult, with its primary center, the site of Chavin de Huántar in the central Andean highlands (Burger, 1996). The Chavin cult used golden objects as symbols of power, status, and participation in the cult, and artifacts with Chavin iconographic and symbolic elements are found widely distributed at sites in the central and northern Andes. For the first time in the Andes, more elaborate forms of artifacts made of gold are found: crowns, ear spools, nose ornaments, plaques, gorgets or pectorals (a plaque suspended in front of the neck; <http://www.metmuseum.org/collection/the-collection-online/search/318334>), bracelets, beads, and effigy spoons (http://static-content.springer.com/image/chp%3A10.1007%2F978-1-4614-9017-3_15/MediaObjects/185051_1_En_15_Fig5_HTML.jpg). Aspects of technology change as well. Although the hammering of thin sheets of native gold dominates goldsmithing technology in Chavin times, new techniques, such as annealing, soldering, sweat welding, and sintering, appear (Lechtman, 2014, pp. 374–375). Further, there appears to be a good understanding of gold alloy composition and use (Burger, 1996, p. 73).

The Early Intermediate period, especially in the northern and central Andes and associated

with sites of the Moche archaeological culture, is witness to a tremendous florescence of metallurgical technology in which gold is used extensively in the context of elite social, political, and religious activities. Although aspects of the Moche polity continue to be debated, it is clear that it was able to mobilize large numbers of people for massive public works programs, including the construction of ceremonial and religious structures. The polity was dominated by an elite social class, and much of the trade and craft production that is evident in the polity was controlled by them. Religion and leadership were very much interconnected.

Substantial quantities of metals, now including copper, silver, and gold, were used as display and status items by these elites. The forms these artifacts took varied considerably: masks, ear spools, and ear flares, (<http://www.metmuseum.org/toah/works-of-art/66.196.40,.41>) simple (<http://www.metmuseum.org/collection/the-collection-online/search/317801>) and complex (<http://www.metmuseum.org/toah/works-of-art/1979.206.1225>) nose ornaments, crowns, necklaces, beads, vessels, and other decorative objects. Thin gold foils were sewn onto tunics and garments. Gold was used in complex inlays, and it was often paired with silver, which has led many archaeologists to surmise that this represented an aspect of Moche cosmology and gender associations (Lechtman, 2014, p. 377; Schorsh, 1998, p. 129). These items were used by the elites in their royal costumes and were found buried with the dead in elaborate tomb constructions filled with metal, ceramics, feathers, woods, textiles, and other materials.

Moche craft workers employed a wide range of techniques in the creation of these artifacts and extensively used a variety of alloys – copper-gold and copper-silver-gold as well as sophisticated soldering, annealing, casting, and gilding techniques. Copper was used in these alloys to stiffen the gold (or silver) to maintain the shape of the artifact (Lechtman, 2014, p. 379). One of these copper-gold alloys – known by the term *tumbaga* – was often used by these artisans to create a gold color for the artifact without the use of significant quantities of gold. More complex artifacts were constructed through the creative

use of mechanical joining techniques – tabs, slots, wires, and hooks – that were often gilded (Schorsch, 1998, pp. 113–117).

Following the decline of Moche and similar cultures around 800 CE, the major polities of the Middle Horizon – Wari in the central Andes and Tiwanaku in the south central Andes – gold continued to be used in elite contexts although in lesser quantities.

Gold returns to prominence in the activities of the elite in the Late Intermediate period and Late Horizon. In the former, the Chimor of northern Peru accumulated vast quantities of gold artifacts of all kinds, and their metallurgical technologies rivaled those of the Moche in their complexity and variety. One of the motivations for the accumulation of so much gold was due to their political organization. Chimú emperors warehoused their treasures in large *ciudadelas* – walled compounds that enclosed their living quarters, ritual precincts, storehouses, and eventually, mortuary complexes into which they were placed after death. The descendant of the emperor, usually a son, inherited the title, but not the accumulated treasures of his father. In time, he would create his own *ciudadela* and fill it with treasures accumulated through his own military conquests and trade relationships.

The Inca arrive in northern Peru around 1470 CE and conquer the Chimú and almost every other polity in Andean South America from southern Ecuador to northern Chile. With roots in the Cuzco basin of the central Andes, the Inca create a vast empire and in the process collect not only treasures but perhaps, more importantly, the artisans that created them. The Inca looted the Chimú *ciudadelas* of their gold and used it in their own religious and status systems. The Inca emperor was the embodiment of the sun, and gold was seen as the material manifestation of this belief. Gold was used to craft vessels, articles of clothing, decorations, jewelry, and more. The Inca expanded metal production of all kinds for state purposes and accumulated gold and other precious objects through tribute payments by vassals from across the empire.

Perhaps the most ostentatious use of gold by the Inca was in the Qorikancha, or Temple of the

Sun, which was located in central Cuzco. The temple was situated in what the Inca believed was the “pivot of the universe” (Moore, 2014, p. 435) and was composed of a set of four structures surrounding a large plaza. The interior walls of the temple structures were covered in massive sheets of gold (for an imaginative digital reconstruction of the interior of the temple, see <http://commons.wikimedia.org/wiki/Category:Coricancha#mediaviewer/File:Corigold.jpg>). As described by Moore (2014, p. 435):

Using crowbars, the Spaniards pried the gold off the temple walls, removing 700 gold plates, each weighing between 4 and 12 pounds; the gold was hauled away in 178 loads, each carried by four men.

Gold in the form of miniature llamas or deities was also an important element of the Inca ritual of *capacocha*, which involved the sacrifice of children on high Andean peaks (Andrushko et al., 2011).

Although the forms that gold took through Andean prehistory changed significantly, there is one constant that persisted for almost 4,000 years: gold signaled status and some degree of social prestige. Although it was never used as money or coinage, gold signaled the owner's wealth and position within society.

Gold Mining in Mongolia

Mette High

The University of St Andrews, St Andrews,
Scotland, UK

Compared to many other parts of the world, Mongolia is remarkably rich in minerals. More than 6,000 large deposits have been discovered, numbering at least 80 different minerals (Husband & Songwe, 2004, p. 3). The most economically significant of these are gold, copper, molybdenum, and fluorite. The country also has extensive coal reserves, combustible deposits, and gemstone occurrences. Apart from limited hard rock (lode gold) deposits, Mongolia is particularly rich in placer gold (alluvial deposits). These deposits have originated elsewhere and been moved to their more recent locations, often by the force of water or sand. Since placer gold is not geologically integrated with its matrix, it is relatively easy to extract and does not require further crushing, milling, or the addition of chemicals such as mercury or cyanide. Instead companies use various forms of opencast mining and tunneling to extract the placer gold. In areas where water is available, a method known as “hydraulic mining” or “hydraulic sluicing” is used which separates the gold from the gravel. Rockers, trommels [a rotating cylindrical sieve or screen used for washing and sorting pieces of ore or coal], sluice boxes, and other techniques are used in various combinations to recover the

loosened gold. Since many of Mongolia’s placer formations are long, narrow, and relatively shallow, mining companies have rapidly advancing mine faces and, correspondingly, rapidly abandoned mined-out areas. Apart from making the long perimeters harder to police, Mongolia’s “ribbonlike” placer deposits can in some instances be difficult or unprofitable for mining companies to excavate (MBDA, 2003, p. 49). The geological formation of gold thus provides artisanal and small-scale gold miners with lucrative opportunities for both prospecting and mining. Moreover, many mining companies have used technical equipment that was originally developed in the early 1930s in the USSR and therefore not only outdated but also intended for mineralogical conditions dissimilar to those of Mongolia (Farrington, 2000). Given the low gold recovery rates of these companies, they have provided a relatively rich and readily accessible resource for artisanal and small-scale gold miners. When droughts and disastrous weather conditions occurred between 1999 and 2002, causing catastrophic livestock losses among the nomadic pastoralist population, the placer deposits attracted growing numbers of people, and it eventually grew into a nationwide large-scale gold rush.

Placer gold is likely to have been mined as early as the eleventh century in Mongolia (Murray & Grayson, 2003, p. 15). Historical sources describe a long-standing resistance towards mining activities, which were seen to transgress fundamental taboos related to the land (High & Schlesinger, 2010). Amidst local opposition, the first industrial mines were opened in 1899 by the joint-stock mining company Mongolor, which had a recorded production of 771 kg of gold before closing in 1913 due to civil unrest and lack of political support (Atwood, 2004, p. 357). Soviet geological expeditions surveyed the country in 1930–1931, and a systematic mapping of the country’s geology was carried out in 1960, documenting gold deposits in all regions. Only in 1978 did mining become a major branch of the national economy with the opening of a copper and molybdenum mine in Erdenet. When annual gold production figures were made public in 1991, it was recorded

at 722 kg. In 2005 Mongolia's gold production peaked with a recorded annual production of 24,122 kg, making the country the world's top 19th producer of gold.

Mongolia's mineral-rich economy has experienced severe boom and bust cycles in recent years. When global commodity prices and external demand began to plunge in 2008–2009, it shocked the country's economy and exposed its structural volatility. With mineral revenues accounting for one-third of fiscal revenues, 70 % of industrial output, and almost 80 % of exports in 2011, the economy has been at risk of Dutch disease, whereby non-mineral-related sectors of the economy lose their competitiveness from the large mineral sector exports and revenue flows (Reeves, 2011; World Bank, 2012, p. 15). This risk is particularly acute with the 2013 production launch of one of the world's largest copper and gold mines, the Oyu Tolgoi deposit in the South Gobi province (Wacaster, 2012). Measured and indicated mineral resources include more than 650,000 kg of gold and almost 780,000 kg of inferred gold, which is set to make Mongolia one of the fastest growing economies in the world (Ivanhoe Mines Ltd, 2012, p. 13).

In Mongolia mineral resources are the property of the state. In addition to numerous laws and guidelines, the Minerals Law of Mongolia regulates the prospecting, exploration, and mining of minerals. However, the existing legislation only confers licensee rights onto registered mining companies and does not explicitly refer to artisanal and small-scale mining activities (High, 2012). In 2001 and 2002, the government attempted to accommodate informal sector mining by enacting interim regulations, but they proved largely ineffective and were not renewed. In subsequent years, the government drafted an Artisanal Mining Law, which failed to gain parliamentary approval and was abandoned in August 2005. New drafts have since been prepared, but to date, none has been approved. According to a Swiss-funded project that seeks to enable the formalization of artisanal gold mining in Mongolia, there is much reluctance among both government agencies and artisanal miners to

support the formalization efforts. The main challenges have been lack of desire to pay income tax and limited access to viable mining land for miners (Singo Patience, 2011, p. 5). At present, according to the Law, artisanal gold mining is thus still considered an illegal activity.

Artisanal gold miners in Mongolia are locally known as "ninjas." Their use of a green plastic panning bowl, carried strapped to their backs on walks to and from the mines, apparently triggered this colloquial name. Their silhouettes were said to be reminiscent of the television cartoon series called *Teenage Mutant Ninja Turtles*, popular in Mongolia at the time when informal sector mining surged (Grayson, 2006, p. 1). There is a wide range of opinions about the number of artisanal gold miners in Mongolia. This variation stems in part from the large size of the country, the practical difficulties of counting the number of artisanal miners at any given site, and the substantial seasonal fluctuations in their geographical distribution. According to published government figures, there are about 30,000 artisanal gold miners, but independent surveys suggest this to be a significant underestimate, proposing figures of at least 100,000 artisanal gold miners or 20 % of the total rural work force (MBDA, 2003, p. 18; Navch, Bolormaa, Enhtsetseg, & Munhjargal, 2006, p. 17). In addition to these, there are also smaller numbers of artisanal miners involved in the extraction of other minerals and rocks, such as fluor spar and coal (Baatar & Grayson, 2009; Grayson & Baatar, 2009).

Given the scale of formal and informal sector gold mining in Mongolia, the environmental consequences are already severe. Dredges, settling ponds, and panning beds have affected rivers, contaminating them with sediments and other pollutants (Suzuki, 2013). Groundwater resources have been removed at a rapid rate, and dumps of topsoil, waste rock, and tailings have been left without any environmental rehabilitation (World Bank, 2006, p. 16). Since mining typically uses land and water resources more extensively than other industries, conflicts of interest have become increasingly frequent and fierce. Much of the opposition to the impact of mining has been voiced through "river

movements” that draw on and highlight people’s close ties to the locality as an economic, social, and cosmological basis for their livelihood (Upton, 2012). As in the past, gold mining, in its various forms, is also today considered a profitable, yet contentious, activity in Mongolia.

Gou-Gu Theorem

Joseph W. Dauben

One of the basic theorems of geometry in both the ► **East and West** concerns the relationship between the sides of a right triangle and their squares, known in the West as the “Pythagorean” theorem, but understood in an equivalent form as the *Gou-Gu* theorem in China. The ancient Egyptians, Babylonians, and Chinese probably discovered this remarkable property of right triangles by empirically examining the simplest case of 3-4-5 triangles. Whether in its geometric form or more familiar algebraic expression, $3^2 + 4^2 = 5^2$, the theorem concludes that the sum of the squares on either “side” of the right angle is equal to the square on the hypotenuse (Xian). In China, this was established for right triangles in general, i.e., not just for the 3-4-5 triangle, or for those with sides of integer lengths. The Greek made this discovery as well, but proved it rather differently in the argument presented at the end of the first book of Euclid’s *Elements*, Proposition I-47.

One of the great treasures of Chinese mathematics is the *Jiuzhang Suanshu* (Nine Chapters on the Art of Mathematics). It is the final chapter that is the most famous, in which the *Gou-Gu* theorem is introduced. Even before the *Nine Chapters* was written, results dealing with right triangles had been presented in an earlier astronomical-mathematical work, the ► *Zhoubi Suanjing* (The Arithmetic Classic of the Zhou Gnomon). The *Nine Chapters*, however, goes well beyond the simple applications found in the *Zhou Gnomon* text, which is concerned primarily with applications in astronomy. In fact, Chapter 9 contains 24 problems, each of which deals primarily with right triangles and solutions of quadratic equations. One of these is a variation on one of the oldest of China's mathematical problems (this is Problem 6 in Chapter 9 of the *Nine Chapters*) (see Fig. 1):

In the middle of a pond that is ten “chi” in diameter, a reed grows one “chi” above the surface of the water. When pulled toward the edge of

the pond, the reed just reaches the perimeter. How long is the reed?

The solution to this problem is a straightforward application of the *Gou-Gu* theorem.

In commenting on a passage from the *Nine Chapters* that reads, “Combining each square of *Gou* and *Gu*, taking the square root will be *Xian* (the hypotenuse),” Liu Hui explains the *Gou-Gu* theorem as follows:

The *Gou*-square is the red square (*Zhu fang*), the *Gu*-square is the blue square (*Qingfang*). Putting pieces inside and outside according to their type will complement each other, then the rest (of the pieces) do not move. Composing the *Xian*-square, taking the square root will be *Xian* (the hypotenuse) (Guo, 1990).

The reference to moving pieces inside and outside is related to a diagram, no longer extant, and makes use of the so-called “Out-In” method which was taken as an axiom by ancient Chinese mathematicians. The power of this axiom can be seen, however, from the following illustration, where the two triangles ABC and ACD are equal (Fig. 2):

Since the areas I and I', II and II' are equal, then it follows from the “Out-In complementary principle” that III must be equal to III' (Wu, 1983).

Gou-Gu Theorem, Fig. 1 The *Gou-Gu* theorem based upon the $Xian\ Tu = Xian$ diagram, meant to accompany the *Zhoubi Suanjing* (see Fig. 3). Note that the square AHJC on the hypotenuse of the right triangle ABC is comprised of 25 unit squares, equal to the sum of the two squares on each side of the triangle, ADEH (16 unit squares) and CBFG (9 unit squares) (Drawing by the author)

Gou-Gu Theorem, Fig. 2 A problem that can be solved by applying the *Gou-Gu* theorem (see text: How long is the reed?) (Drawing by the author)

Gou-Gu Theorem, Fig. 3 The *Xian* figure

This now helps to explain Liu Hui's commentary on the *Gou-Gu* theorem. First of all, his references to colored squares are similar to colors mentioned in the diagrams illustrating the *Gou-Gu* theorem in the *Zhoubi Suanjing*. There, in the "*Xian* figure," the central square is yellow, while the squares of the *Xian* square are red. Often the *Gou* square is blue (Fig. 3).

Applying the "Out-In" complementary principle to the *Xian* figure, and following Liu Hui's commentary on the *Gou-Gu* theorem, the sum of the squares based on each leg of the right triangle ABC, namely the squares ADEB and BFGC, is equal to the square of the hypotenuse AC, namely the square AHJC (see Fig. 1 above). In accordance with the "Out-In" principle, if we move those parts of the two small squares (ADEB and BFGC) that are on the outside of the large square (AHJC) to its inside, we can see that they fill the inside exactly and that the combined areas of the two small squares equal that of the larger one. Since the areas are analogous to the squared sides of the triangle, the sum of the squared legs equals the squared hypotenuse.

It has been argued that geometry never developed further in China than it did with Liu Hui's commentary because this was sufficient for Chinese needs. After Liu Hui, Chinese geometry does not seem to have made much further progress. Although some authors suggest that this was due primarily to the practical orientation of ancient Chinese mathematics, it may have been

its actual success, its comprehensiveness, that caused the stagnation of any further development. As D. B. Wagner has suggested:

Liu Hui's conceptual framework was adequate, for example, to deal with a much broader range of geometric solids than those which he actually considers in his commentary. Had he felt a need to push his methods to their inherent limits, he would surely have contributed a great deal more to the mathematical tradition. Here we can see the double influence of the enormous prestige of the *Chiu-chang suan-shu*: it provided a challenge and an inspiration; but it was often a strait jacket which confined the interests of mathematicians to certain specific problems.

Like Euclid, Liu Hui summarized his art so successfully that his successors may have felt little need, or room, for improvement.

Gunpowder

Ho Peng Yoke

Gunpowder was probably discovered in China accidentally. Since the Han period (202 B.C.E.–A.D. 220) Chinese alchemists attempted to make gold or to prepare an elixir of immortality. Sulfur and saltpeter were among the raw materials used for their experiments, and charcoal was among the different types of fuel used in their laboratories. The *Zhenyuan miaodao yaolue* (Classified Essentials of the Mysterious Dao of the True Nature of Things), a book of the late Tang but probably containing material from much earlier dates, carries a note of caution to the alchemists warning them to exercise due care when dealing with sulfur, saltpeter, and charcoal because there were cases where the operators had their hands scorched or their thatched huts set on fire.

In China gunpowder found its early use in amusements, in religious and ceremonial functions, taking the form of fireworks and rockets, and in construction works, such as blasting rocks in the opening of waterways and roads. For

example explosives were used by Gao Ping to open a rocky water route linking Guangdong province and Annam in the ninth century. There are no records that show the use of gunpowder in the battlefield before the tenth century. An early fire weapon that the Chinese used was the “incendiary arrow” (*huojian*) to send a variety of ignited substances to the enemy camp. At first naphtha was one of the combustion agents used. By 919 there appeared the force pump that could throw flaming petrol, or “Greek Fire,” directed toward the enemy. Both naphtha and “Greek Fire” were imports from the West.

The *Songshi* (Official History of the Song Dynasty) mentions that in 970 Feng Jisheng submitted to the emperor a report on the manufacture of “incendiary arrows” and that in 1000 Tang Fu made “incendiary arrows,” “fire balls” (*huoqiu*), and “thorny fire balls” (*huojili*). These were bombs and grenades containing gunpowder for hurling over enemy walls and camps by means of trebuchets. Later on the bombs progressed from those with weak casings to those with stronger ones.

In the middle of the tenth century the “fire-lance” (*huoqiang*) was invented. At first it consisted of a ► [bamboo](#) tube with its septa cleared. Then it was filled with rocket composition and capable of shooting out flames horizontally. According to Needham the “fire-lance” had enormous repercussions in China for some 700 years from the middle of the tenth century, playing prominent roles in many battles. It also marked a transition from the bulky petrol flame-thrower to a much lighter and portable weapon using gunpowder, and heralded the use of the principle of the tube in ► [military technology](#). Bamboo tubes gradually gave way to barrels made of metal. The “fire-lance” took a big step forward in 1259 when the “fire-emitting lance” (*tuhuoqiang*) was developed. This type of “fire-lance” could fire scrap metal and break porcelain, if not also small darts or arrows, on which poison was sometimes applied. The range of the projectiles was short compared to a single bullet from a gun barrel. The Chinese later developed a

similar firearm with a large barrel mounted on a carriage, rather like a field gun but which emitted a large quantity of projectiles instead of a single shell. Again these projectiles could be scrap metal, stone, broken porcelain, arrows, and poisonous or noxious substances.

The earliest document giving the gunpowder formula and describing its applications in various forms of firearms is the Song military compendium, *Wujing zongyao* (Collection of the Most Important Military Techniques), written by Zeng Gongliang in 1044. It describes with illustrations a number of weapons using gunpowder, such as the grenade, the bomb, etc. and gives several gunpowder recipes. The compositions suggest that the earlier Chinese gunpowder was more of the deflagratory type. A much higher ratio of saltpeter for explosives was used later.

Around the year 1000, gunpowder weapons were deployed on the battlefield in China. Large quantities of gunpowder were prepared and stored up during the Northern Song (960–1126). In 1232 the “thunderclap bombs” were brought into action. In the early twelfth century knowledge of gunpowder was acquired by the Jurchen people who eventually occupied northern China and established the Jurchen empire (1115–1234). In 1232 they used the “thunder-crash bomb” and the “flying fire-lance” (*feihuoqiang*) to defend their capital Bianjing against the Mongol invaders. Bianjing fell the next year. Gunpowder and firearm technicians were captured by the Mongols and taken into their service. The Mongols invaded Europe from the year 1236, deploying firearms of the offensive type. For example trebuchets were used on at least two occasions, in July 1237 at the battle of Ryazau, and in July 1241 “incendiary arrows” were used at the battle of Wahlstadt. The Mongols also used their firearms against the Arabs. In 1258 they used “fire-jars” to attack Baghdad, probably a reference to the thunder-crash bombs, which the Mongols also used against the Japanese in a sea battle near Kyushu in 1272. The next important city to fall after Baghdad was Damascus. The

Muslims set up the Mamluk caliphate in Cairo and in 1260 defeated the Mongols in a battle in Syria. From then on, the two sides made little headway against each other for some years, during which the Mamluk caliphate turned its attention to military affairs and weaponry. Some Mongolian soldiers surrendered and some firearms and technicians fell into the hands of the Muslims. The Muslims thus acquired the technique of making firearms. They used them successfully against the Sixth Crusade (1248–1254).

By the latter part of the thirteenth century the narrow cylindrical tube of the fire-lance had already developed into one with much wider bore for the cannon (*huopao*). For example cannons were deployed when the Mongolian fleet went to Java in 1292 and 1293. Many examples of Chinese cannon, both of bronze and iron, are known from 1330 onward. Several types of cannons are described in the fourteenth-century military book, the *Huolongjing* (Fire Dragon Manual).

During the second half of the fourteenth century Chinese firearms were unmatched anywhere in East Asia. They were used by Zhu Yuanzhang, the founder of the Ming dynasty, to overthrow the Mongols and to suppress local rebellions. After his victory he kept his firearms in secret arsenals. There was no need to improve these weapons as they met no challenge, so that he only saw the necessity of guarding both the weapons and the knowledge from falling into undesirable hands. This happened during a period when Europe was undergoing great social change and when European firearms began to come to ascendancy. Traditional Chinese weaponry is now something of the past, but firework displays that we see on auspicious occasions around the world today remind us of the original role played by gunpowder in China.

Guo Shoujing

Ho Peng Yoke

Guo Shoujing (1231–1316), an astronomer, mathematician, and hydraulic engineer, was born in Xintai (in modern Hebei province). The names of his parents are not known, although records show that his grandfather, Guo Yong, was knowledgeable in the classics, in mathematics, and in water works. As a boy of 14 Guo Shoujing was able to construct an advanced type of clepsydra, or water clock, for his time: the *lianhuailou* (lotus clepsydra), so named because the top of the receiver was in the shape of a lotus flower. In about the year 1251 he restored an old bridge across the Dahuoquan River north of Xinzhou, also in Hebei.

In 1260 Guo accompanied his friend Zhang Wenqian (1217–1283), who was sent by Qubilai Qan to Daming to pacify the local population. There he began to construct astronomical instruments, such as a bronze clepsydra and a ► [bamboo](#) armillary sphere. The same year Zhang Wenqian recommended him to Qubilai for his expertise on irrigation. Guo was soon commissioned to improve irrigation and water communication within the region south of the capital Dadu (modern Beijing) and north of the Yellow River. The mission was successfully accomplished. In the year 1264 Guo again accompanied Zhang to the Circuit of Xixia

(in modern Gansu province) to restore the irrigation canals that had been blocked or damaged during the years of war. He reported on what he saw during his travels and made many recommendations to Qubilai on the improvement of irrigation and water communication systems.

There was an urgent need to reform the existing calendar, the *Damingli*. In 1276 Qubilai captured the Southern Song capital, Linan (modern Hangzhou) and thought that the time was ripe to promulgate a new calendar. Guo and Wang Xun (ca. 1235–1281) were commissioned to lead a special bureau established for the project. Guo Shoujing built 17 new astronomical instruments to obtain more accurate astronomical observations on which the accuracy of the new calendar would depend. Thirteen of the instruments were used in the capital Dadu, and four were used for fieldwork. In 1279 Qubilai established an Astronomical Bureau at the capital. Zhang Wenqian was appointed Director, while Guo and Wang Xun were made the two co-Directors. A new observatory was built at the capital along with new bronze astronomical instruments. Guo organized a large-scale measurement of the length of the shadow of the gnomon cast by the sun in different latitudes, from the capital in the north to Nanhai (modern Guangzhou) in the south, to determine the length of the meridian.

Guo used spherical trigonometry and the method of finite difference involving a cubic equation to do his calculations. The new calendar, the *Shoushili*, was completed in 1280. This was the most accurate calendar ever made in traditional China. It was promulgated the next year. Guo Shoujing was promoted to the Directorship of the Astronomical Bureau.

In 1292 Guo held a joint appointment as head of the water works bureau in the capital. The same year he constructed water locks and canals linking various cities to the capital. The Qan was greatly pleased on completion of the project. While he was in the capital Guo made a clepsydra whose bells and drums would chime and sound

on the hours for his master. After the death of Qubilai, Timur also sought Guo's advice. Guo died in 1316.

H

Ḥabash Al-Ḥāsib

Lawrence Souder

Ḥabash al-Ḥāsib was one of the earliest Muslim astronomers and a major contributor to the development of trigonometry. He was born in Marw, Turkestan (modern Mary, Turkmenistan) and died between AD 864 and 874. Ḥabash lived during the Abbasid empire, when the caliphs became the stewards of civilization. This empire preserved ancient science and philosophy by translating ancient Greek, Syriac, Sanskrit, and Persian texts into Arabic. Ḥabash himself based his work and methods on Ptolemy's *Almagest*. Ḥabash held Ptolemy in high regard, calling him "the wise Ptolemy" and describing his work as having the "utmost in research and precision" (Langermann, 1985). Ḥabash led the way in the Arabic development of astronomy and computational techniques.

As an astronomer Ḥabash worked at calculating more precise celestial distances and at developing more accurate ways of calculating these distances. He calculated such values as the circumference of the earth, the diameter of the moon, and the distance of 1 min along the orbit of the sun. Ḥabash's work in trigonometry consisted of calculating tables of trigonometric values and developing new trigonometric functions. He calculated tables (called *zījes*) of sine values at 1° intervals to

three places, and he is considered to be the first to construct a table of tangent values.

In Ḥabash's time much of Muslim science served the needs of the religion. For example, Islam requires the faithful to face Mecca when they pray. To this end Ḥabash developed an analemma, or graphical, method for finding the azimuth to Mecca, called the *qibla*. Muslim calendars were dependent upon the appearance of the new crescent of the moon. Ḥabash is thought to be the first astronomer to calculate when the new crescent appears. Islam also requires the faithful to make a pilgrimage to Mecca. Ḥabash once calculated what he called the distance "by the straight arrow," or the great-circle distance between Baghdad and Mecca to be 677 miles, while the actual overland distance was known to be about 712 miles. In one of his few surviving works, *Kitāb al-ajrām wa-l-ab 'ad* (The Book of Bodies and Distances), Ḥabash reported that ► [al-Ma'mūn](#), the caliph at the time and Ḥabash's patron, was pleased with the small difference between the two distances considering the uneven terrain between the two cities.

Hair in Egypt

G. J. Tassie

The ancient Egyptian hairstylist was expected to be able to style hair, as well as cure baldness, make hair (of a rival) fall out, get rid of head lice and cover up the signs of aging by dyeing grey hairs. Ancient Egyptian clients would also require more mundane tasks, such as cleansing and scenting the hair.

Tinting

The Egyptians used natural dyes which are known to coat and partially penetrate the hair’s 6–14 layers of cuticles. These natural semi-permanent tints do not leave roots as they wash out of the hair, although a virtually permanent tint may be achieved with frequent application. The main colour the Egyptians would probably have wanted to achieve was black, emulating the dark brown colour of their youthful hair. One recipe was an ointment made of juniper berries and two unidentified plants kneaded into a paste with oil and then heated. The natural blue-purple colouring agent in the plants would rub off on the hair, while the astringent properties of the

juniper would stimulate the scalp (Manniche, 1989, p. 46).

Indigotin (*Isatis tinctoria*) is a blue dye that is found in both indigo and woad, and is an obvious choice for Egyptian hair dye as indigo occurs naturally across much of northeastern Africa. There is considerable epigraphic evidence to suggest that deep blue-black was the colour towards which most Egyptians aspired, and this is the colour that is achieved by putting blue dye on the Egyptians’ natural dark brown hair. This would have been used on both the person’s own natural hair and on hair used to make wigs, as Fletcher (1995) has found traces of indigotin on both. Indigotin also has antiseptic properties and was widely used all over the Middle East on clothing and directly on the skin. As the Egyptians had considerable expertise in so many natural medicines, they are unlikely to have been unaware that trichological (hair science) application of indigotin had a positive side effect as an anti-bacterial agent. On one of the two blonde-haired mummies Petrie found at Gurob was a large black sprang (sprang is closely related to braiding, but it is done on threads which are stretched on a frame, so that the braided fabric builds from both ends towards the middle) headcover that he claimed was worn to cover the person’s own blonde hair, possibly to hide the fact that the individual was foreign (1890, p. 39). However, Fletcher’s examination of the hair and headcovering revealed the fact that the blonde hair had been enhanced with yellow henna, and that the sprang headcover was dyed a dark blue-black using indigotin and a small amount of madder (1995, p. 469).

The later periods of Egyptian Pharaonic history saw the use of tannin to tint hair a dark brown colour, usually in conjunction with iron mordents (Fletcher, 1995, p. 469). A mild form of natural bleach may have been used to enhance or define a style, or to pre-lighten the hair so it could be dyed a brighter colour (Fletcher, 1992, p. 16). Such a substance may have contained natron and lemon juice, a lightening substance that is still used today.

Henna (*Lawsonia inermis* L.; *Lawsonia alba* L.) was also used in the Pharaonic era, but

it would be unwise to use this to support the oft-made assertion that Egyptians commonly used henna to dye their hair, as we know that that black (see above) rather than red was the favoured hair colour in ancient Egypt. However, while red was seen as being a dangerous colour for most of Egypt's history, henna was certainly used as a hair colorant (although probably not widely) by the higher echelons of society at least. This is reinforced by the iconographic record and actual wigs and hair of mummies, which show very little use of henna up to the end of the New Kingdom (1069 BCE). Brunton suggests that the light red-brown hair of an elderly woman from the Badarian (4500 BCE) cemetery at Mostagedda might have been brought about by an application of henna dye (1937, p. 45). Smith believes that the brilliant reddish colour of Henttawy's hair and the dark reddish-brown hair of Thutmose IV were tinted with henna (1912, pp. 19 and 44). However, it should be considered that various types of henna produce different colours, from yellow through to nearly black, and that other ingredients can be added in order to produce different effects. The yellowish hue of Ramesses II's hair is not the result of the mummification process, as once believed, but was the result of henna or one of its derivatives being applied to the King's grey hair (Balout, 1985, p. 256) to resemble the King's natural hair colour in his youth.

The hair of Nesikhons was found to have been "thickly strewn with powdered red resin" (Smith, 1912, p. 109). A similar case of a coloured powder being used in this manner was found on the hair of the mummy of the Priestess Tansertemsutenpa, who was found with a thick coat of yellow ochre over the top of her hair, possibly concealing a small bald patch as well as colouring the remaining hair (Smith, p. 158). While it may be difficult to distinguish intentional dyeing ingredients from naturally occurring materials that inadvertently found their way into the hair, it has been suggested that a small sachet of a fine dark powder, manganese dioxide and quartz – found in the wigmakers workshop at Deir el-Bahari – was sprinkled over the hair for

cosmetic reasons (Laskowska-Kusztal, 1978, pp. 119–120).

Hair Care

The hair of an ancient Egyptian woman was literally her crowning glory as can be attested to by a number of literary and epigraphic sources where men's apparent fascination with long, sweetly smelling dark hair is made abundantly clear. However, if women had a vested interest in keeping their hair in good order for the benefit of men, it is also evident that men also wished to boost their trichological endowments, paying considerable attention to the many medical recipes for the care and restoration of hair. There is a whole section within the Ebers Papyrus that concerns baldness, hair preservation and general welfare of the hair and scalp, including this one to prevent baldness: "castor oil; the fat from a hippopotamus, cat, crocodile, snake and an Ibex and rub this mixture on your head" (Wreszenski, 1913 Spell EB 465). The care of the scalp usually involved various oils such as castor oil or moringa oil (*ben* oil) mixed with other ingredients. Another hair treatment for maintaining the good health of the hair (and scalp) was prepared from "a red mineral; kohl; myrtle berries (?); oil or fat; gazelle dung and hippopotamus fat, mixed to make a paste" (Manniche, 1989, p. 125 Spell EB 471). The most effective ingredient was the oil, which moisturised and nourished the scalp at the same time making the hair feel soft and smooth and look shiny and healthy. The red mineral and kohl may have also added a slight dark reddish hue to the hair.

Head lice (*Pediculus humanus capitis*) were a common parasite in ancient Egypt, and were a major cause of head shaving because washing alone does not kill or remove them from the hair. Head lice are particularly common in children and live just behind the ears and in the nape of their host's head, preferring clean hair to dirty or oily hair. The Egyptian habit of oiling the hair may have had a preventative effect on louse infestation (Dayagi-Mendels, 1989, pp. 76–78), while many other parasites like fleas and flies

were trapped by the glutinous substances (including beeswax and resin) which were used to set the hair. Both the Hearst and Ebers medical papyri contain possible recipes to remedy louse infestation or “*hnsyt*-illness of the head”, such as this one: “fruit of the castor-oil plant; ox fat; moringa oil. Combine and mix into a paste, use as an unguent every day” (Wreszenski, 1913 Spell EB 437; Hearst 24). The term *hnsyt* has been translated as “that which moves about on the head”. The application of the ointment would probably have improved the condition of the ailment; in the case of head lice it would not only remove the adult lice, but loosen the egg cases as well. While we do not know the composition of all the ancient Egyptian oils used, natural insecticides such as quassi, derris, sassafras and stavesacre (Fletcher, 1995, p. 39) may have been used, probably in collaboration with the de-nitting combs mentioned above.

Highly diluted natron (Natron was a salt (sodium carbonate and sodium bicarbonate) that was used in the mummification process to dry out the body of the deceased in order to assist in its preservation) may have been used as a detergent for dissolving greasy deposits when washing the hair (Ghalinoungui, 1983, p. 153), as a fragment of this substance was recovered from the wigmakers’ workshop at Deir el-Bahari, and tests confirmed that it still retained its detergent properties (Laskowska-Kusztal, 1978). The use of these harsh detergents may explain why some women had bald patches.

Ancient Egyptians used beeswax and resin to style their hair, although this appears to have been done every few weeks rather than on a daily basis. Beeswax is commonly found in hair and wigs, and as it seems unsuitable for oiling or perfuming the skin, it is probable that it was used to set the hair (possibly at a ratio of 2/3 wax to 1/3 resin (Fletcher, 1995; Lucas, 1962)). It is unlikely that this mixture of wax and resin comprised the “scent cones” popular in the New Kingdom, as the body/environment would have been unable to reach the melting temperature of wax (60 °C = 140 °F) in order for it to melt naturally and flow over the hair and body. Lucas therefore concludes that the wax and resin mixture must have been

warmed up first and then rubbed into the hair and as it cooled set it in style (Lucas, p. 31).

From Late Neolithic times (4500–3050 BCE) to the Graeco-Roman Era (332 BCE–AD 306), both men and women would scent and oil their hair. The oiling of the hair to keep it supple and pleasant smelling was done on a daily basis as part of the morning toilette ritual. Lucas’ (1962, p. 89) examination of residues found in cosmetic containers found palmitic and stearic acids, which probably represented perfumed ointments made of animal fat mixed with scent. The most frequently cited hair oil was a substance known as *Qemi*, which came from the Red Sea region and found widespread use in the anointing of aristocratic coiffures throughout the New Kingdom. The importance of keeping the hair in good order cannot be overstated, judging from the frequent literary references made to divine hairstyles. For example, in “The Song of the Perfumed Hair”, the fragrant locks of the Goddess Shentayt are alluded to thus: “There is perfume, there is perfume in your hair, O holy Shentayt, perfume in your hair” (Nachtergaeel, 1981, p. 593). In the New Kingdom tomb of Rekhmire the harpist sings: “Put myrrh on the hair (or curls) of Ma’at” (Davies, 1943, pp. 60–61). There is also mention of oils being poured over people’s hair during the Old Kingdom (2613–2181 BCE), such as in the Dynasty V tomb of the Vizier Senedjemib where an inscription states that King Djedkare Isesi “Caused that I be anointed with fat” (Breasted, 1907, p. 122).

Although scented oils could be rubbed into the hair by hand, scent cones are commonly depicted in New Kingdom art (Fig. 1). Scenting or festal cones were first introduced into Egypt during the Middle Kingdom (2040–1650 BCE), where they are depicted on a Dynasty XIII (ca. 1795 BCE) stela relief of Amenysenb from Abydos, where his Asiatic brewer Irsi is seen wearing a smallish lump of unguent on his cropped hair (Fletcher, 1995, p. 446). However, scent cones only start to be depicted in any real number from the reign of Hatshepsut (Dynasty XVIII, from 1473 to 1458 BCE) and become even more popular during the reign of Amenhotep III (1390–1352 BCE).

H

Throughout the New Kingdom (1550–1069 BCE) and up to the Ptolemaic Period scent cones were worn (Maraite, 1992). They are most frequently represented on tomb scenes, but can also be found on temples and stelae reliefs (Maraite). A sculpted version can be found on figures of nobility such as the statues of Neferhotep and his wife (Davies, 1932, frontispiece) and Khay and his wife (Muhammed, 1966, pl. 8). Cones are sometimes shown being worn by *ushabtis* (Ushabtis were small figurines made from wood or clay, or occasionally stone or ivory. Often the ushabtis were depicted with tools, or in some act of work. They were buried with Egyptians, so that, if the deceased were called to work in the afterlife, the ushabti would take the deceased's place performing the task), i.e. those of Tuty (Kozloff & Bryan, 1992, p. 259). The ancient Egyptian name for these cones was *bt*. The cones were worn by men, women and children alike, and they were not just limited to the elite classes, but are shown being worn by musicians, dancers and servants as well. Although Fletcher (1995, p. 446) has proposed that they were just symbolic of the scenting and oiling of the hair, some Nubian

peoples (Bisarin) are known to wear similar scented cones (Keimer, 1953, p. 342 ff.). Although in later depictions they become highly stylised and unrealistically tall and thin, it is likely that a small, round tablet of scented animal fat was indeed placed on the hair at banquets and other festive occasions to keep the hair sweet smelling and in good condition. The custom of using scent cones was probably introduced into Egypt from Nubia because of the Egyptian expansion into the region during the Middle Kingdom (2040–1650 BCE).

In ancient Egypt, there was an emphasis on being or looking young, fit, healthy and able. This emphasis is demonstrated by the king having to prove his fitness to rule by running the *heb sed* court on his jubilee. Receding or greying hair is rarely depicted in tomb scenes, particularly on the elite, although the lower orders were sometimes shown in this manner to mark the social distinction between them and the tomb owner (Janssen & Janssen, 1996; Robins, 1996). The various remedies against baldness and concoctions to colour greying hair show that the youthful ideal was not just an artistic principle but a pivotal part of Egyptian socio-economic culture.

The maintenance of the black hair of one's youth was equated with vitality, fertility and potency; receding (completely bald or shaved heads reflected piety and cleanliness) and grey hair were symbolic of disempowerment.

Hair in Egypt: People and Technology Used in Creating Egyptian Hairstyles and Wigs

G. J. Tassie

The practice of hairstyling in Egypt can be traced back to the Predynastic Period (4000–3050

BCE), and was accompanied by a series of technological changes reflecting this new tradition, especially copper and bronze tools. The oldest tools were bone and wood combs and hairpins, with flint or obsidian blades being used to cut the hair. Although hairstyling was initially mainly utilitarian, Egyptian society's growing complexity led to a proliferation of more extravagant styles. Like most other social status markers, hairstyles helped to maintain and reinforce a person's social position and maintain their privileged access to goods and materials (Trigger, 1993). Hairstyles can therefore be grouped with body decoration, clothing, and jewelry in that they all inform the onlooker as to gender, age, status, class, sexuality, ethnicity, and ritual affinities (Fletcher, 1995; Robins, 1999; Tassie, 2002).

There are five main operations that can be performed on hair:

1. It can be curled or left curly;
2. It can be straightened or left straight;
3. It can be plaited, twisted, or teased;
4. Hair can be added; and
5. Hair can be taken away.

These five operations may be used separately or in any combination. Accessories may also be added, including hairpins, combs, and fillets. (A fillet is a ribbon or narrow band of fabric worn around the head across the forehead, as an ornament or to hold back the hair.) Tinting of the hair may also occur, although this does not come into the above categories of hairstyling. The ancient Egyptians also developed wigs and hairpieces to supplement their own hair, enabling them easily to change their hairstyles to suit the occasion. However, the use of the term "wig" to describe all ancient Egyptian hairstyles is incorrect. Certain statues depict the owner's own hair protruding from beneath a full wig (particularly in the Old and New Kingdom) but other depictions of figures, such as those on the Erotic Papyrus and many of the workers in the fields and other secular tomb scenes are clearly not wearing wigs (Fig. 1). Therefore, unless one is certain that the person is actually wearing a wig, the term

Hair in Egypt: People and Technology Used in Creating Egyptian Hairstyles and Wigs, Fig. 1 Close-up of the head of Nofret showing her real hair exposed beneath her full, bobbed wig. Meidum, Dynasty IV, Old Kingdom (Photograph by author copyright Egyptian Museum of Antiquities, Cairo)

H

"hairstyle" should be used. Wig manufacture and wearing are discussed further below.

The types of hairstyles worn by men and women changed throughout time and space. The social significance of hairstyling became codified after the period of unification, allowing only certain status groups to wear particular hairstyles. Constraints were placed upon the choices of hairstyles that individuals were allowed to wear both by society and the technology open to the ancient Egyptian hairstylist. The hairstyles that a person could wear were temporally dependent upon a person's social position and status. A form of sumptuary laws existed in Egypt regulating social etiquette with regards to what forms of hairstyle were permissible by various classes and statuses of individuals at certain occasions. These laws were not written down but were governed by social and courtly modes of behavior. The hairstylists through their creation of hairstyles and wigs helped to perpetuate the hegemonic situation and reinforced the social relations, even when creating new styles.

During the Old Kingdom shaved heads were sported by both men and women of all status groups, as well as cropped hairstyles. Short,

Hair in Egypt: People and Technology Used in Creating Egyptian Hairstyles and Wigs, Fig. 2 Dyad of Meryneith (Meryre) and his wife Iniura, found in his Saqqara tomb by the Dutch Mission. His title is the “Scribe of the Aten Temple in Akhetaten and Memphis.” Her titles are “The favorite and Beloved Wife” and “The Great Lady of the House.” Note the more naturalistic rendering of hair at this period in three-dimensional art; Meryneith has a duplex style and Iniura a gala hairstyle. Amarna Period, Dynasty XVIII, New Kingdom, Saqqara, now in the Cairo Museum (Author’s own photograph? copyright Egyptian Museum of Antiquities, Cairo)

round, curly styles were primarily worn by low to middle class men. The various lengths of bobs were worn by both elite men and women, although with slight variations in the actual dressing. The long tripartite hairstyle was worn by women of any class, but only sacred men (i.e., gods, kings, and the dead). The tripartite hairstyle was symbolic of fertility and rejuvenation. Therefore women as child bearers and sacred men (king – Egypt’s fertility, deities – humanities creation, and fertility and the deceased – rebirth) were allowed to wear the style. During Dynasty XVIII (1550–1295 BCE) the gala hairstyle was introduced for elite women, as was the duplex style for elite men. The Nubian hairstyle became popular just before the Amarna Period of the New Kingdom (1352–1323 BCE), during the reign of Amenhotep III, and remained the standard elite hairstyle of both men and women until the reign of Horemheb (1323–1295 BCE) (Aldred, 1957). The classic children’s hairstyle – the sidelock of youth – remained popular throughout Pharaonic history (Tassie, 2005) (Fig. 2).

The Ancient Egyptian Hairstylist and Barber

Due to hair’s apparent social importance, many hairstylists and barbers plied their trade throughout ancient Egypt. The elites usually had a hairstylist attached to their staff or arranged for one to visit their homes, whereas poorer people would go to a traveling hairstylist. For everyday care and attention, the elite women would have had a maidservant trained to do the dressing. Poorer people would have to rely upon a relative or friend to style their hair. The work of the barber (*h’ky*) was not thought to be as highly skilled as that of the hairstylist. Barbers would set up beneath the shade of a tree, placing their stools, and cutting the hair of their clients. Tomb scenes and inscriptions from the Old Kingdom (2613–2181 BCE) the Middle Kingdom (2040–1650 BCE) the New Kingdom (1550–1069 BCE) and Late Period (646–332 BCE) bear witness to the fact that certain hairstylists held a high social rank (Gauthier-Laurent 1935–1938). All except two of these inscriptions refers to men. The word used to describe him is *ir-šn(y)*; the rarely found feminine form is *irt-šn(y)* – literally hairmaker, hairdoer, or wigmaker. There is usually a modifying determinative after the word *ir-sheeny*, denoting that the bearer of the title was either a “royal hairstylist” or an “overseer of hairstylists” (Riefstahl, 1952, 1956). Other related words are *nšt*, hairdresser, and *nšy*, which means “to dress hair.” These words are used occasionally from the Middle Kingdom onwards, but usually refer to a casual hairdresser. In ancient Egypt hairstylists were frequently important officials who held important offices in addition to their tonsorial duties (Riefstahl) (Fig. 3).

Wigmaking

Although many publications refer to any Egyptian hairstyles as “wigs,” true wigs were in fact fairly rare, and then almost exclusively the preserve of the elite. That the rulers of the proto-kingdoms were probably using extravagant

H

hairstyles, wigs, and headdresses to signify status is evidenced by the elaborate hairstyle of the elite Naqada II (ca. 3600 BCE) woman in Burial 16 at HK43. This is the earliest palaeoethnobiological evidence for the wearing of false hair so far recovered in Egypt. The hair was shoulder length, tinted with henna, and augmented with a considerable number of false hair swatches. The finished hairstyle was very voluminous with matted tresses (reminiscent of modern dreadlocks) and with a lot of height. Another Naqada II female mummy from Hierakonpolis (Burial 333) had what we now call a Mohican-type hairstyle. (The author has only seen a photograph of this hairstyle and has not examined the mummified remains. Mohican-like was how the director of Hierakonpolis – Dr Renée Friedman – described the hairstyle in a lecture. The modern-day Mohican hairstyle is shaved at the sides with a line of hair sticking up from the center of the skull, like a cockerel's comb, whereas a Mohawk is shorter and normally squared off with the central section of hair starting just above the occipital bone. The photograph of the hairstyle in Grave 333, HK43 did not appear to have shaved sides but was

combed into the medial line of the head giving a Mohican-like appearance to this hairstyle.) Also found at Hierakonpolis HK43, in the double burial 154, is the oldest toupee so far found in Egypt – early Naqada II. This hairpiece was made of either “goat or sheep's wool” and had been secured in place over the bald patch of an elderly man's scalp by weaving strands of the man's own hair into the hairpiece (Friedman, 2001, p. 12). The intricacy of the styling techniques involved in creating these styles indicates that it took many hours of work and was probably performed by a professional hairstylist (Fletcher, 1998). There is also epigraphic evidence of wig wearing. On the famous pair of Dynasty IV (ca. 2613 BCE) statues of Rahotep and Nofret from Meidum, Nofret's own hair can be seen combed flat beneath a full bob wig. Archaeologists found a wig dating from the First Intermediate Period (2181–2040 BCE), in the Dynasty VIII tomb of Hefefi at El-Hagarsa. This wig was shoulder length and black, consisting of long, straight braids made of twisted flax fiber and set with beeswax and resin (Kanawati, 1993, pp. 21, 65). The archaeological record shows an increase in

the number of wigs surviving from the Middle Kingdom; notable examples include the numerous wigs found in their original wig boxes in the Dynasty XII (1985–1795 BCE) tombs at Lisht. These wigs were made of human hair and were styled into long braids (Lansang, 1933). The records show a dramatic increase in the amount of false hair that survives from the New Kingdom, as do subsequent periods. However, there is evidence that the wearing of wigs fell out of favor during the Late Period (Fletcher, 2000a, 2000b).

Human hair was the main material used for constructing wigs and hairpieces, sometimes in association with date palm fiber, reeds, and linen (especially during the Graeco-Roman Period – 332 BCE–AD 306; Tassie, 2002). No animal hair was ever used (apart from the HK43 toupee) (Eisa, 1953; Lucas, 1930, 1962), and in every case except that of Maiherpri, cynotrichous (Caucasian) rather than heliotrichous (Negroid) hair was used in wig construction (Fletcher, 2000a, 2000b). There are epigraphic indications that wigs were valuable assets: they were listed alongside gold and incense in the account lists from Kahun (Fletcher, 2000a, 2000b), while a single wig (probably of fiber) constituted two-thirds of a woman's dowry in a marriage contract from 219 BCE (Tassie, 2002). Although false braids could be made from the wig owner's own hair, the vast amount of hair used in wig manufacture was probably shaved from the heads of foreign captives or was sold to the wigmakers by its impoverished prior owners. Hair was traded extensively throughout the Roman Empire, and was sufficiently valuable to cause a specific custom duty to be paid on it (Fletcher, 2000a, 2000b).

Once the hair had been processed, cleansed and detangled, it was ready to be made into wigs and postiches (hairpieces). The processed lengths of hair would then have been styled into plaits, curls, and wefts before being fastened directly onto the head or onto a wig foundation. The wig foundations were usually made of plaited hair (or, more rarely, incorporating leather straps and linen strings) as an open-mesh base or a series of knotted wefts of hair. These mesh bases and wefts were then often sewn on to

a linen cap with a drawstring, so that it could be secured to the head (Tassie, 2002). There was considerable variability across time and space in terms of wig manufacture. For example, Merit's wig consists of wefts of hair knotted together to form a kind of marteaux or diamond mesh around a medial plait with a central parting (Chiotasso, Chiotasso, Pedrini, Rigoni, & Sarnelli, 1992), while the British Museum wig is composed of some 300 locks of hair (each containing about 400 hairs) on a foundation of finely and tightly plaited human hair forming a hair net with rhomboidal apertures (Fig. 4).

The root end of each lock was secured by looping it around part of the mesh, pressing it back against the hair stem and fastening it with substrands of the root section; this was then locked in place with beeswax and resin (Cox, 1977). The greatest collection of ancient Egyptian wigs is in the Egyptian Museum of Antiquities, Cairo where there are 23 full wigs and numerous hairpieces (Tassie, 2002). The Egyptians protected their wigs by keeping them in wig boxes, such as Merit's large rectangular cupboard-like wig box found in her husband Kha's tomb in Thebes with poles to hang the wig from (Chiotasso et al., 1992) or Tutankhamun's square wig box found in his tomb KV62 with a mushroom-like stand in the center for hanging the wig on (Reeves, 1990, p. 193) (Fig. 5).

While our knowledge of wig morphology and structure is considerable, the details of the wig construction process were unclear until the discovery of a wigmaker's workshop dating to between 1800 and 1700 BCE in a crevasse overlooking the Temple of Mentuhotep II at Deir el-Bahari. The workshop contained four alabaster vases in a linen sack with various wigs in different stages of production, tufts of hair, hair wefts (on threads), swatches (tied up with fibers), and a thread net-foundation. A papyrus case found in the workshop held a bronze awl, five bone hairpins, and fragments of two flint knives. In another container were pieces of linen (probably for the skullcap), solid soda "soap," leather straps, bone beads, and other oddments. A unique model head made of wood was also

Hair in Egypt: People and Technology Used in Creating Egyptian Hairstyles and Wigs, Fig. 4 Wigs in the Cairo Museum: (a) left to right: lady Istemkhebs short curly wig – JE26252h, duplex wig – JE26252g, Ahmose-Hentempet short curly wig JE46913; (b) wig of thick triple braids (JE23412) found in side-chamber of Amenhotep II's Tomb (KV35), New Kingdom and Third Intermediate Period (Photographs courtesy Joris van Wetering ? found and is believed to have been used for laying out the wigs while in production. Black lines had been traced to show the outline of the wig's attachment and its long and short axis (Laskowska-Kusztal, 1978).

Hair in Egypt: People and Technology Used in Creating Egyptian Hairstyles and Wigs, Fig. 5 Large wig box recovered from the tomb of Yuya and Thuya in the Valley of the Kings, Thebes. It is made of papyrus stalks supported by reeds, and measures 107 cm long by 51 cm deep. The box stands on four reed legs, and had an outer lid, and an interior double leaved lid opening from the middle to form a tray. This lid was tied down with linen thread and sealed with black clay seals. The front of the wig box is ventilated by three windows, one at each and the other in the middle of the front panel. The wig box may originally have held Yuya's duplex wig CG51185, which was found in a niche in his tomb KV46, Dynasty XVIII, New Kingdom, Cairo Museum (Photograph courtesy Joris van Wetering ? Copyright Egyptian Museum of Antiquities, Cairo)

Hairstyling was not done for fashionable reasons but was used to convey the class and status of the wearer. However, the hairstyles of the ancient Egyptians were far from static, and evolved to express changes in Egyptian society. This flux gave rise to a large assemblage of tools, unguents and hair products that can be seen in many of the world's museums, along with the mummies whose hair was treated in the ways discussed above. Some museums may hold only a hand-mirror or a razor, whereas others, such as the Metropolitan Museum of Art, New York include whole wigs in their displays of ancient Egyptian hairdressing and beauty paraphernalia.

The art of hairdressing was already well developed by 3000 BCE in Egypt. The social importance of hair was such that ancient Egyptian hairstylists were highly regarded, especially those allowed to work on the hair of the pharaoh.

There was even a goddess of hair and hairstyle (Khonsut) and a god of the royal beard and barbers (Duwar).

Acknowledgments I would like to express my gratitude to Dr Lawrence Stuart Owens for his editorial skills and also to Ms Janet Johnstone for her encouragement and comments on this entry and my other entries in this volume.

Hairstyling Technology and Techniques Used in Ancient Egypt

G. J. Tassie

Three types of cutting equipment were available to ancient Egyptian hairstylists: the razor, the “composite tool” (a combination of scissors and hair-curler) and the comb. Of these, the razor was the main implement used for cutting the hair. The hairstylist would probably take the bulk of the unwanted hair away using the razor, using a bodkin (hairpin) to separate the hair not being worked on. They would then work on the free section, sculpting with the razor and snipping off any stray hairs with the scissor part of the composite tool before releasing the next section to be cut. The process worked around the hairline first, then up to the crown. The client would view the results in a bronze hand-mirror (Fig. 1).

Microscopic examination of the cut ends of hair on wigs and mummies has revealed the majority to be of the tapered variety and very clean-cut (Fig. 2). This indicates that it was cut with a sharp razor while wet (Fletcher, 1994a), as the razor requires the lubrication of water to make it glide over the hair and give a clean cut. There are modern parallels: many Indian hairstylists and barbers use a razor against a piece of wood, combing the hair flat across the wood, then pulling the razor across it to give a straight line and a smooth-looking finish to the style. However, no depictions of ancient Egyptian hairstylists cutting long hair have been found, so the method employed must remain just supposition at the moment.

After cutting, the next step was plaiting or curling the hair. The former would probably be done wet, whilst the hair would be dried before carrying out the latter. The curling would be done using curling-tongs (composite tool), then dressed and set using beeswax and resin and an assortment of hair accessories such as combs,

Hairstyling Technology and Techniques Used in Ancient Egypt, Fig. 1 Scanning electron microscope (SEM) photographs at 1,100 $\times$ magnification of Romano-Christian hair, ca. third century AD, Egypt. The ends of the hair in this period have been cut using scissors

leaving a blunt end. The cortex (central part of hair) and medulla (middle segment of hair shaft) have virtually disappeared due to calcification, which can clearly be seen on the surface of the cuticles (outside layers) (Photo by author)

hairpins or more ornamental head dresses (Fig. 3).

Tools Available to the Ancient Egyptian Hairstylist

The Razor: Form and Development

The copper razor (*s3*) had its beginnings in the Protodynastic Period (3350–3050 BCE). It was probably derived from the copper flaying knife (Petrie, 1917) rather than the lithic “razor” which was no more than a side scraper. Originally there were two types of razor: an asymmetrical variant with a single lateral cutting edge and a symmetrical spatula-like tool (Fig. 4a) with parallel sides and a rounded cutting edge (Davies, 1977, p. 110). The asymmetrical type soon fell out of use, and by the end of the Old Kingdom (2613–2181 BCE) had been almost completely replaced by the symmetrical type. This form went through a series of variations; in general terms, the sides proceeded to splay out (Stead, 1986, p. 50) throughout the Old Kingdom.

During the Middle Kingdom (2040–1650 BCE) the cutting edge of the symmetrical razor began to protrude laterally (Fig. 4b). Coming in at

Hairstyling Technology and Techniques Used in Ancient Egypt, Fig. 3 Hair ornaments of Princess Sithathoriunet, a daughter of King Senusret II, Dynasty XII, Middle Kingdom, found with other jewels near her father's pyramid at Lahun now in the Cairo Museum: (a) Gold diadem; (b) Gold tubular hair ornaments that were threaded on the tresses of hair (Photo by author copyright Egyptian Museum of Antiquities, Cairo)

this time (Dynasty XII, 1985–1795 BCE) is the scalpel-like razor or *dg3* type razor (Davies, 1977). This type was made of a thin strip of metal (Fig. 4e), sharpened at one end, which later incorporated a loop (often in the form of an animal, bird or deities' head), in which to rest the

little finger in order to help rotate the razor (Petrie, 1917, p. 50). By Dynasty XVIII (1550–1295 BCE), the *mh'k* razor – one of the most characteristic pieces of toilette equipment of the New Kingdom (1550–1069 BCE) – had evolved into a hatchet-like form, with a wooden handle almost at a right angle to the cutting edge and a spur projecting from the rear of the razor. This is thought to have served as a counterweight, to ensure proper balance and handling (Stead, 1986, p. 50) and also as a little finger rest. Petrie called this type of razor the (horizontal) rotating razor (Fig. 4c). The rotating strip metal razor resembled the later splayed symmetrical razor and proceeded to evolve throughout the New Kingdom, with small varieties becoming more popular. Eventually the symmetrical razor evolved into a vertical rotating form, with its cutting edge splaying out even more to form a half-moon arc (Fig. 4d). By the end of the New Kingdom (ca. 1069 BCE), the rotating razor had superseded the scraping form. From the Middle Kingdom the handles of the scraping form were made in increasingly ornate forms, and by the New Kingdom the handles displayed zoomorphic designs and representations of deities of love and birth such as Bes and Taweret.

The Razor-Usage

The early razors were all of the scraping variety and were used with the hand grasping the handle or the end of the cutting edge (which was either on the inferior or lateral aspect of the tool). The development of the strip and rotating razor saw a technical change: the razor was grasped in the middle of the blade (by the handle or the blade itself) and rotated around the grip in a sawing motion, pushing the cutting edge through the hair. Epigraphic evidence and razor morphology suggest that the stylist would shave off the bulk (or all) of the hair using the large rotating razor and would possibly even style the hair/wig with it as well. The small razor was probably for personal use, and for the precision cutting of the intricate areas of the head and body that the larger razor could not safely reach. The inclusion of both types of razor in the toilette sets of the New Kingdom – such as those of Tutankhamun

Hairstyling Technology and Techniques Used in Ancient Egypt, Fig. 4 Examples of the various types of razors: (a) Spatula razor, symmetrical, parallel sides and ivory handle (UC 40660) – scraping type, Old Kingdom; (b) Protruding or axe-shape razor (UC 40539) – scraping type, Middle Kingdom; (c)

Horizontal rotating razor (UC 38368), New Kingdom; (d) Vertical rotating razor (UC 30134) with the God Bes for the handle, New Kingdom; (e) Looped strip metal rotating razor with goose head as handle (UC 40657), New Kingdom (Photos by author copyright Petrie Museum of Archaeology, University College London)

(Davies, 1977) and Kha and Merit (Schiaparelli, 1927) – seem to support the differing functions of the *mh'k* and *dg3* razors (Davies).

Razors were sharpened on a whetstone made of tapered grained crystalline stone, (i.e. quartzite, diorite, basalt or even hard sandstone) using water and/or oil as a lubricant. To stop the razor becoming blunt too quickly, it could be kept in a wooden razor case inside a leather pouch or case.

The Composite Tool (Curling-Tongs) and Tweezers

Other types of tools were available for the removal of unwanted hair, including tweezers and the

composite tool. Tweezers are known from Dynasty I (ca. 3050 BCE) onwards; they had either pointed or squared ends, and varied in length from 2 to 10 cm, depending on the part of the body they were to be used on. The tweezers are made of a single piece of copper, bronze, iron or – more rarely – gold. The shape of the tweezers varied from triangular with sharp ends to more ornate varieties with paddle-like ends (Petrie, 1917). These tweezers were easily bent out of shape, so were often set around a tapered bone, ivory, stone or wooden block that was shaped to fit the interior of the tweezers and thus prevent them from being misshapen (Fig. 5a). Tweezers would be used to

Hairstyling Technology and Techniques Used in Ancient Egypt,

H

remove any hairs not completely shaved off by the razor and to shape the eyebrows.

The most peculiar tool used by the Egyptian hairstylist was the composite tool or curling tongs, consisting of two metal (bronze) elements pegged together with a pin. One element is a trough-shaped piece of metal pointed at both ends, while the other element has a flat knife-like blade at one end and a cylindrical point at the other (the latter was sometimes omitted and replaced by a zoomorphic figure – Petrie, 1917). The knife-like blade fit neatly into the other section, and could thus be used like scissors, while the other ends acted like tongs (Fig. 6a). As well as curling tongs, these instruments could also be used as a razor or as scissors, for cutting off any stray ends. These composite tools are found from Dynasty IV onwards and vary in size from about 5 to 20 cm in length, with various circumferences for giving different-sized curls. They were not as effective as scissors – which are not found until the Roman Period – because the cutting edges were not sharp enough and do not meet precisely enough for this purpose. As Petrie (1917, p. 49) notes, the knife-like blade was the least important part of the tool, as it is diminished or is entirely absent in some later forms, being replaced by

figures of a running jackal, galloping horse, running leopard, a pelican, or crane (with the hinged opening representing the jaws) or the Goddess Taweret (Fig. 6b). Some rather large knife-like blade types are found in Dynasty XVIII, and were used as curling tongs. The technique involved heating the tool over an open fire or brazier in order to set the curl, but this must have been tempered by a hot plate or boiling water – to avoid burning the hair – as the tongs show no sign of having been exposed to open flames. Some of these tools may have been set in wooden handles, as suggested by a gift list in the Amarna Letters, which states, ‘29 spatulas of silver with handles of boxwood and ebony with which one curls the hair’ (Kozloff & Bryan, 1992, p. 428). Another indication that these tools were indeed used to curl hair is an example in the Manchester Museum which still has a curl of hair attached to it.

Combs and Hairpins

Pins and combs were used to keep the hair in place whilst it was being dressed, cut or styled, and for decorating it afterwards. These implements have their origins in the Predynastic but seem to have become very popular throughout the Pharaonic Period, where numerous combs and

Hairstyling Technology and Techniques Used in Ancient Egypt,

Fig. 6 New Kingdom composite tools from the Petrie Museum of Archaeology: (a) Large, plain composite tool (UC 40664); (b) Panther and lotus blossom decorated medium sized composite tool (UC 30134) (Photographs by author copyright Petrie Museum of Archaeology, University College London)

hairpins have been found in association with other beauty (cosmetic) equipment in houses and tombs throughout the country. The majority of well-provenanced combs are dated to the Ramesside Period (1295–1069 BCE) (Kozloff & Bryan, 1992, p. 360).

The ancient Egyptian word for comb was originally *nšī*, but this changed in the New Kingdom, where the “n” was replaced by a “p” to give *pšī* or “divider” (Janssen, 1975, pp. 178–9). Combs were usually made of wood, ivory or bone. The choice of material and design suggest that they were designed to bend slightly in order to avoid splitting, some incorporating a long handle and a tapering effect from the top of the handle down to the tip of the teeth. Predynastic combs tended to be fairly ornate in design, and were sometimes made in two pieces and with large grip handles (Fig. 7a, b). The handles were often elaborately decorated and could constitute up to $\frac{3}{4}$ of the comb’s total length, while the teeth lengths and widths were also highly variable. One comb with extremely long teeth of Naqada I date (3900–3700 BCE) is now in the Bolton Museum, No. 76.09.5 (Adams, 1988). However,

predynastic combs with very narrow handles and short teeth have also been discovered (Petrie, 1896). Pin-tail combs first appear in the Naqada I Period, and consist of a square comb (usually of wood or ivory) with a long, thin “tail” protruding from the middle of the comb’s body (Fig. 7d). This type of comb could be used as decoration in the hair with the teeth keeping it in place or to style the hair, the tail being used to tuck in the hair tips and arrange the hair, to select sections of hair to be styled or even for scratching the scalp.

Bird designs were by far the most popular motif in the Early Predynastic Period: a particularly fine example of an ivory comb with a double bird emblem is now in the British Museum, EA 18666. Spade and wild animal motifs were also present in the Naqada I Period; two ivory examples can be seen in the British Museum (EA 63075 – spade, and EA 63406, ibex). Anthropomorphic, zoomorphic and animal-headed designs including cow (probably the Goddess Bat or Hathor) headed designs increased in popularity during the Late Predynastic, although all designs were present throughout

the period (Adams, 1988; Garetto, 1955). Early Dynastic combs tend to be shorter with the teeth cut more closely together, some as close as 2 mm (Garetto), although some large ornate examples can still be found. One of the finest examples of such a comb (assigned to King Djef) has a very large handle, a centrally positioned niche palace facade *serekh*, with two *was*-sceptres and an *ankh* on the sides (Fig. 7c). The teeth of the comb are fairly fine and not very long in comparison with the handle (Emery, 1961; Garetto, 1955).

Old and Middle Kingdom combs were simplified, with the handle becoming thinner and the teeth relatively longer, more similar to modern combs except for the highly ornate decoration with semi-precious stones or faience beads (Fletcher, 1995, p. 441; Garetto, 1955). From the New Kingdom onwards, comb designs became increasingly variable, generally becoming more ornate and with more stylistic categories. The comb's teeth start to vary in length, width and spacing, reflecting the fact that they were designed to serve different purposes rather than the all-purpose combs of earlier eras. The combs with short, closely spaced teeth would have been used for denitting and grooming. The combs with long, widely spaced teeth were primarily designed to be worn in the hair (as reflected in their usually high level of

decoration) once it was dressed, or for detangling the hair. The intermediate form (medium length, intermediately-spaced teeth) would have been used to comb the hair into style. A fine wooden example with incised lotus petals on the handle, originally with blue paste filling the spaces, was found at Abusir el-Malek. Measuring 17 cm long by 5 cm high, this comb is dated to Dynasty XVIII, JE 36233 – CG 44316 (Freed, 1987, p. 182). Other examples of these simple combs were found in the tomb of Kha. The two small combs belonging to his wife Merit were 7.5 × 4 cm and were undecorated, except for a slight trace of gilding (Garetto). Rectangular double-sided combs without any handle also appeared in the New Kingdom and were usually designed to be multifunctional with closely spaced teeth on one side and widely-spaced teeth on the other (Fig. 7e). Pintail combs also reoccur in the New Kingdom.

Hairpins or bodkins were usually made from ivory or wood and measured between 10 and 16 cm. They derived their Egyptian name (*3b*) from the term for ivory *3bw*, although they were also made of copper, bronze, bone, or sometimes tipped with gold or other precious metals. Predynastic and Early Dynastic hairpins were often ornately decorated with zoomorphic or anthropomorphic figures and geometric designs (Fig. 8). The Old Kingdom and Middle Kingdom

hairpins tend to be less ornate, with a simple engraved top, minimal (or absent) incised decoration and a bulbous or pommel head. While plain pins were used throughout Egyptian history, the range of new designs and decorations in New Kingdom pins is marked. Made from a range of materials including gold (both leaf and solid), elite versions were often decorated with zoomorphic or anthropomorphic designs. Precious metal examples include several gold hairpins that were found in Kha’s tomb (Schiaparelli, 1927), while a fine example of a well-executed zoomorphic design in ivory is that of a hairpin head upon which an ibex turns her head with affection to observe her suckling calf. The recurring image of the ibex (i.e., the comb mentioned above) reflects the importance of Hathor to rituals of beauty and the artefacts related to those rituals. This fine hairpin is 9.5 cm long and is exhibited in the Boston Museum of Fine Arts (Freed, 1981).

The hairpins were used both to dress (keeping locks in place) and to decorate (after dressing) the hair. Depictions of hairpins in use are again rather limited, although more numerous than those depicting combs. One of the finest examples is the Middle Kingdom hairdressing scene where Queen Neferu’s maidservant Henut has pinned

the top section of her mistress’s hair out the way with an ivory bodkin whilst weaving a braid into the hair (Riefstahl, 1956, p. IX).

By the middle of the Old Kingdom, the increasing availability of copper tools meant that ancient Egyptian hairstylists were able to cut, curl, tint, set, and plait the hair in numerous ways. As technology and alchemy progressed and the Egyptian empire expanded in the New Kingdom, hairstylists developed new styles as well as various ways to perfume and dress the hair fostered by emulation and increasing social complexity (Table 1).

Hardaliye

Fatma Çoşkun

Namik Kemal University, Faculty of Agriculture, Food Engineering Department, Tekirdag, Turkey

Hardaliye, a traditional beverage produced by fermentation using lactic acid bacteria, is manufactured from red grape or grape juice added with crushed mustard seeds and preserved with benzoic acid (Figs. 1 and 2). It is a popular beverage especially in the Thrace region of Turkey. It is produced by red scented grapes such as ripe Hamburg Misketi or Madam Mathies. Production of that drink begins when the grape harvest starts in October or November. After the grapes are washed and pressed, put preferably into wooden (or plastic) barrels with a tap over 10 cm from the bottom, then 0.2 % of crushed raw mustard seeds and 0.1 % of benzoic acid are added. In order to enhance the aroma, crushed cherry leaves can be mixed with black mustard seeds. Since grapes are fermented with their skins, there are transitions of some particles from the skins to the drink during production. There should be some space left in the fermentation barrel considering the swell. The lid of the barrel should be half-open. After fermentation starts, the juice is recirculated twice every other day; then the mix is left to ferment at room temperature for 7–10 days. If the ambient temperature is low, the fermentation process can be

Hardaliye, Fig. 1 Hardaliye produced from red grapes

extended up to 20 days. After fermentation is done, the juice is filtered and bottled. Once fermented, the hardaliye is stored at 4 °C for 3–4 months (Arici & Coskun, 2001; Coskun ve Arici, 2006). The hardaliye is consumed either fresh or aged. If it is aged, hardaliye may contain alcohol.

The mustard seeds' etheric oils affect the yeasts (Akgul, 1993). Due to the contribution of black mustard seeds to both taste and aroma of hardaliye and their superior inhibitory effect, black mustard seeds (*Brassica nigra* (L.) Koch) may be more suitable for the production of hardaliye. White mustard seeds (*Brassica alba* (L.) Boiss) can be also used in this process. The active ingredient of the volatile oil is allyl isothiocyanate. Black mustard essential oil includes ratio of 0.40 :1.80 % allyl isothiocyanate. White mustard seed contains very little volatile oil. Benzoic acid inhibits or decreases alcohol production by affecting the yeast (Jay, 1992, Krämer, 1992).

Hardaliye, Fig. 2 Hardaliye produced from White grapes

The Importance of Hardaliye and Studies on Hardaliye

Fermented foods are important components of daily diets in many parts of the world. Microorganisms (bacteria, molds, and yeasts) play an important role in the fermentation processes. Final products have often undergone considerable changes. These changes are not only because of microbial action but also because of the autolytic process that is brought about by the enzymes which exist in the products. Therefore, fermentation serves the purpose of preparing a fully acceptable, palatable, safe, and mostly very nutritious food at a relatively low cost (Hesseltine, 1979, 1981; Hesseltine & Wang, 1979; van Veen & Steinkraus, 1970; Wang & Hesseltine, 1981). Many fermentation processes are carried out by lactic acid bacteria (LAB) which inhibit

many other microorganisms when they are cultured together. This is the basis of the extended shelf life and improved microbiological safety of lactic-fermented foods (Jay, 1992). In some Middle Eastern countries, lactic acid-fermented fruits and fruit juices such as lactic acid-fermented grape juice, fermented cherry, and medlar are common drinks (Aktan, Kalkan, & Yucel, 1999).

The nutritional value of hardaliye is derived from the grapes and the fermentation process. After fermentation the vitamin content of some fermented foods increases. These types of foods are important in terms of nutrition. Fermented foods formed by the lactic acid bacteria have negative effects on the cholesterol formation mechanism that is one of the biggest causes of heart disease. Lactic acid bacteria have a positive effect on the immune system. Lactic acid bacteria support immunoglobulin A and gamma interferon production. This enhances the antitumor activity of lactic acid bacteria. The lactic acid bacteria taken to the digestive tract together with fermented food reduces the activity of enzymes such as the β -glucuronidase, azotoreduktaz, and nitroreductase in the intestine. Pro-carcinogenic substances are converted to carcinogens with the help of these enzymes (Turantas, 1998). Grapes are rich in phenolic contents. One kilogram of grapes contains 12–15-mg quercetin, less than 2-mg kaempferol, 4.5-mg myricetin, 19-mg catechins, and 1–3-mg coumaric acid (Shahidi & Nacz, 1995). Antioxidant flavonoids such as quercetin reduce the oxidation of low density lipoproteins and cell toxication (Luzia, da Paixão, Marcilio, Trugo, Quinteiro, & de Maria, 1997). Flavonoids are anticancer radicals. They stop the process of cell division. Flavonoids prevent heart attacks by preventing formation causing damage to blood vessels (Anonymous, 1988). Grapes contain resveratrol that has antioxidant properties. In a study, resveratrol reduced skin tumors in mice by 88 % (Geoffrey et al., 1988). Dark red grape juice contains about four times more antioxidants than orange and tomato juices (Carper, 1999).

Studies on hardaliye are under way. The pH of hardaliye is approximately 4.5 at the end of fermentation. *Lactobacillus plantarum* is the dominant species in the microbiota (Arici, Coskun, Celikyurt, Mirik, Gulcu, & Tokatli, 2012). Possible probiotic lactic acid bacteria are used in the production of hardaliye, so it makes the drink a more valuable functional product. Pasteurization might be considered for longer shelf life. For a long shelf life and standard product, studies should be done on starter cultures. Selection of starter culture, pasteurization norms, storage conditions, and time created a new process. In a study, changes in hardaliye samples were examined after storage for 1 year. Decrease in pH, Brix, total phenolic, monomeric anthocyanins, and number of microorganisms and an increase in acidity and levels of invert sugar of samples were observed (Coskun, Arıcı, Celikyurt, & Gülcü, 2012).

Conclusion

Hardaliye is produced in a limited number of provinces and manufactured with nonstandard methods. A standard method should be determined to increase the shelf life of this product that is valuable due to its probiotic properties. There should be more research about this nutritious traditional drink in order to produce it industrially. By using standard culture it is possible to have a standard product. Therefore, hardaliye produced with traditional methods at home, which is very healthy and nutritious and has a relatively short shelf life (3 months), can be industrialized and its shelf life can be extended. The development, increase, and diversity of technological production are possible with the development of traditional methods by the help of scientific research. It is important that the best grape type, the type of the starter culture, and the process parameters should be determined in order to have a desired standard product. If small-scale producers succeed in the production with a starter culture, it might be adapted to large-scale production.

Haridatta

Manu V. Devadevan

Archive India Institute, Bhubaneswar, Odisha, India

Haridatta was an astronomer who introduced the Parahita system that was popular for a long time in astronomy in Kerala and Tamil Nadu. He expounded this system in two of his works, the *Grahacāranibandhana* and the *Mahāmārganibandhana*, of which only the former is extant. There is no positive information about his date or provenance. A late tradition claims that the Parahita system was promulgated in the year 683 CE during the twelve-year *māmāṅkaṁ* (*mahāmāgha*) festival held at Tirunāvāya on the banks of Bhāratappuḷa in Kerala. This is unlikely, as there is no historical evidence for *māmāṅkaṁ* celebrations before the fourteenth century. It may, however, be tentatively accepted that he came from Kerala or Tamil Nadu, as the Parahita system is not known to have existed in any other parts of India. We may also agree with David Pingree that “683 is not an unreasonable date for Haridatta” as he is already cited by Govindasvāmi’s *Prakaṭārthadīpikā* in the ninth century.

Haridatta was trained in the Āryabhaṭa school of astronomy, in which methods of computation were complicated. The Parahita was an attempt to simplify the calculations in the *Āryabhaṭiya* for the benefit (*hita*) of everyone (*para*). The first known use of the *kaṭapayādi* notation is also found in his work. This system, devised to facilitate easier memorization, consists of notations in which numbers are replaced by alphabets in the reverse order. Consider the expression *gorasaṁ rasavārya*. It contains seven syllables, the numbers assigned to them being 3, 2, 7, 2, 7, 4, and 1 respectively. In the reverse order, it produces

the number 1,472,723. Similarly, the four syllables of *girituṅga* yield 3, 2, 6, and 3, which represents the Kali year 3623. It is not unlikely that *kaṭapayādi* was a brainchild of Haridatta's.

Astronomic calculations in India often involved identifying the number of days that have elapsed since the beginning of the Kaliyuga or the Mahāyuga (which is the four yugas put together). This made computation lengthy and cumbersome, as it involved multiplication and division of numbers that were seven to ten digits long. Haridatta overcame this difficulty by introducing a shorter yuga of 576 years (or 210389 days, conveniently remembered by the *kaṭapayādi* notation, *dhījagannūpura*) to substitute for the longer figures. He also made zero corrections in relation to the mean motion of the sun, the moon, and five planets. The choice of 576 seems to have been guided by considerations that are not fully clear to us. The length of the Kaliyuga, Dvāparayuga, Tretāyuga, and Kṛtayuga (or Satyayuga) are 432,000 years, 864,000 years, 1,296,000 years, and 1,728,000 years, respectively, and that of the Mahāyuga, 4,320,000 years. Haridatta's sub yuga is 1/750th, 1/1500th, 1/2250th, 1/3000th, and 1/7500th of these yugas, in that order.

In spite of introducing the sub yuga in which the number of days did not exceed *dhījagannūpura*, the use of lengthier numbers remained an invariable part of computations. One of the computations involved dividing the number of days elapsed in the Kaliyuga by the number of days elapsed in the sub yuga. The quotient indicated the number of sub yugas elapsed, and the remainder, the number of days remaining in the current sub yuga. Haridatta's zero corrections for different planets, when multiplied by the quotient, gave the mean for the respective planets at the beginning of the sub yuga. A further step toward simplifying computations involved the use of units equivalent to six sub yugas where longer time periods were involved.

A major intervention of Haridatta's was the *Śakābdha saṃskāra*, or corrections to the positions, both mean and real, of the planets. He also introduced corrections to the calculation of their

velocities. The zero year for this correction was 523 CE, indicated by the *kaṭapayādi* notation *vāgbhāva* or *vibhava* (deciphered as year 444 in the Śaka Era, and hence the name *Śakābdha saṃskāra*). Haridatta suggested that a correction had to be introduced for every year after the zero year for the mean position of the planets. These corrections yielded figures that were closer to the real values obtained through modern methods, as can be seen from the following table (based on K. Chandra Hari) which shows the mean longitudes at sunrise in Ujjain on Friday, 25 March 931 CE.

Planet	Mean according to Āryabhaṭa's constants	Mean according to Haridatta's corrections	Mean according to modern methods
Sun	00°00 ¹	06°49 ¹	06°42'27 ¹¹
Moon	40°54 ¹	46°58'11 ¹¹	46°54'16 ¹¹

Hasdai Crescas

Tony Lévy

Hasdai ben Abraham Crescas (1340–1412) was one of the most influential personalities of Spanish Jewry in the end of the fourteenth century. As chief rabbi of the Aragonian Jewish communities during the persecutions of 1391, he was responsible for their reconstruction. Although his literary work was not very large, it constitutes an important contribution to the history of philosophical and scientific ideas, mainly as a critique of medieval Aristotelianism.

Under the influence of Maimonides' *Guide for the Perplexed* (translated from Arabic into Hebrew in the beginning of the thirteenth century), Aristotelianism had spread in Jewish circles, raising many controversies. Besides those who opposed the study of philosophy only on the ground that it undermined religious beliefs, others invoked scientific and philosophic arguments to give support to their own critique of philosophy. Crescas is certainly the most important of the latter critics.

Apart from a short composition, *Biṭṭul 'Iqqarey ha-Noṣrim* (Refutation of the Principles of Christianity), Crescas' main work is his *Or Adonay* (Light of the Lord) completed in the last years of his life. In the first part of this book the fundamental concepts of Aristotle's physics and metaphysics, as adapted by Jewish philosophers, were analyzed and criticized.

Crescas' main purpose was to establish that the existence of God, His unity and His incorporeality could not be fully proved by demonstrative reasoning, as Maimonides had argued: "it is impossible to arrive at a perfect understanding of these principles except by way of prophecy, . . . , and yet it will be shown that reason agrees with the teachings thus arrived at." In this sense, one could say that Crescas did not criticize philosophy as such, but rather the intellectualization of religion by Aristotelian scholastics. Actually, in many respects,

Crescas opposed to Aristotelian philosophical notions other philosophical notions, more relevant – according to him – to the purposes of philosophy itself.

The main importance of Crescas' contribution lies in his critique of Aristotle's concept of the infinite, and its applications to the notions of space, number and time.

There are three main conclusions of Crescas' analysis which are relevant to history of science. The first is in opposition to Aristotle who had argued that the place of a body (i.e., space) was the inner limit of the enclosing body, Crescas asserted that space was prior to bodies and that the place of a body was equivalent to its extension. Thus the existence of a void was not self-contradictory. Secondly, again in opposition to Aristotle who had argued that the universe was finite, because nothing could be infinite, neither a body nor a substance, Crescas claimed that there was no absolute limit to space. Space was an infinite receptacle, which could contain many other worlds. By analogy, space could be thought of as God's omnipresence. Finally, Aristotle and Aristotelians argued that an infinite quantity was impossible, because it would lead to the absurd conclusion of one infinite quantity being greater than another. Crescas' reply was of importance since it could be viewed as anticipating some modern concepts: the relations "equal to," "greater than," and "smaller than" do not apply to the infinite, in the same manner that they apply to finite quantities. Thus, the notion of an actual infinity is not self-contradictory.

Hay'a

F. Jamil Ragep

The Arabic term *hay'a* had several distinct significations when used in the medieval astronomical context. Its basic meaning is “structure” or “configuration”; it was used as such to connote the physical structure of the universe as a whole (*hay'at al-'ālam*) or a distinct part of that structure, as in the *hay'a* of the Earth or of Venus. It also referred to those works of theoretical astronomy in which that structure is dealt with in detail. As part of the phrase *'ilm al-hay'a* (the science of *hay'a*), it came to refer, especially after the eleventh century, to astronomy in a general sense. This is an indication of the importance given to physical cosmography in Islamic astronomy. Here the main focus will be on *hay'a* in the sense of the Islamic astronomical genre devoted to cosmography.

Before proceeding, it is important to note two points. Although the term *hay'a* was occasionally used to indicate a religious cosmology, works on *hay'a* are mainly cosmological in the scientific and not the religious sense. Second, this tradition, though departing from it in numerous ways, owes its origins and inspiration to the Hellenistic scientific tradition.

The main ancient sources for the Islamic *hay'a* tradition were the cosmological writings of Aristotle, in particular his *De Caelo* and his attempt in the *Metaphysics* to give a coherent structure to the models of Eudoxus, and the astronomical writings of Ptolemy, especially his *Planetary Hypotheses*. These works provided the fundamental assumption of Islamic theoretical astronomy, namely that the subject matter of astronomy was the simple *physical* bodies, both celestial and sublunar. An astronomer writing in the *hay'a* tradition was charged with transforming mathematical models of celestial motion, usually those of Ptolemy's *Almagest*, into physical bodies that could be nested, along with the sublunar levels of the four elements, into a coherent cosmography (*hay'a*). Despite the obvious connection and dependence on Greek natural philosophy, this “astronomical” (or external) cosmology was often contrasted with both the tradition of Aristotle's *De Caelo* and the astrological corpus, both of which were held to deal with the essential (or internal) aspects of the bodies. Note that because *hay'a* was intended to give a general picture of the universe, it also dealt with the “configuration” of the four sublunar elements. Thus most general treatments of astronomy after the eleventh century came to have a section on the “configuration of the Earth” that included general discussions of geography.

The prevalent *hay'a* was that the universe was a plenum composed of nine contiguous, solid, spherical bodies called orbs, all concentric with an immobile, spherical Earth. The lowest of these, that of the moon, enclosed the four sublunar levels of the four elements: fire, air, water, and earth. Each of the “concentrics” had embedded within it additional, nonconcentric, spherical orbs called eccentrics and epicycles, the former hollowed-out spheres surrounding the Earth, the latter full spheres within the eccentrics. There was one concentric each for the seven “planets” in the following order – moon, Mercury, Venus, sun, Mars, Jupiter, Saturn – another for the fixed stars, and a starless ninth that was the source of the daily motion. Except for the sun, which was embedded within an eccentric, the planets were

situated on the inside surface of their epicycles. Opinions varied as to how motion occurred but generally this was held to result from a combination of the proper motion effected by the orb's own soul and the accidental motion that was a consequence of being contained inside other orbs. All the celestial orbs were composed of a special fifth element called "aether," unlike the four sublunar elements, it could only rotate with uniform motion. Among the most famous and influential works on *hay'a* were the *Hay'at al-ʿālam* (Configuration of the World) by Ibn al-Haytham (d. ca. 1040), the *Tadhkira fī ʿilm al-hay'a* (Memoir on Astronomy) by Naṣīr al-Dīn al-ṭūsī (d. 1274), and *Al-mulakhkhas fī al-hay'a al-basīṭa* (Epitome of Plain *hay'a*) by al-Jaghmnī (thirteenth or fourteenth century).

Although the above cosmography derived for the most part from Ptolemy's *Planetary Hypotheses*, Islamic theoreticians found much to complain about and proposed numerous alternatives that were meant to reform or supersede his models. In his *Doubts About Ptolemy*, Ibn al-Haytham pointed to certain devices that Ptolemy had introduced in the *Almagest*, such as the equant, that violated the principle of uniform circular motion; as such, it was not possible to physicalize such models in any straightforward way. In the thirteenth century, a number of writers, beginning with Naṣīr al-Dīn al-ṭūsī, who was the first director of the Mongol-sponsored Marāgha observatory, proposed alternative models that were meant to reform the Ptolemaic system. These efforts continued for at least three more centuries and included the work of his colleague Mu'ayyad al-Dīn al-ʿUrḍī, his student Quṭb al-Dīn ► [Al-Shīrāzī](#), Ibn al-Shāṭir, the timekeeper of the Umayyad Mosque in Damascus during the fourteenth century who proposed an astronomy without eccentrics, and a number of people associated with the Samarqand observatory in the fifteenth century.

A much more radical attempt to transform the Ptolemaic system occurred in twelfth-century Islamic Spain. A number of Aristotelians, including the famous philosopher Averroes (Ibn

Rushd), sought a radical reform of Ptolemaic astronomy that would rid it of epicycles and eccentrics altogether. The motivation was to return to a purer astronomy in which there was only a single center of celestial motion. The end product of this movement was the work of ► [al-Bīṭrūjī](#). His system, reminiscent of that of Eudoxus, was not very successful from a mathematical point of view, but it was quite influential in the Latin West.

This was not the only case in which Islamic *hay'a* influenced science in other cultures. Byzantine astronomers were certainly aware of this tradition; we also know of several *hay'a* works that were translated into Sanskrit in the eighteenth century. Given that the *Planetary Hypotheses* was unknown during the Latin Middle Ages, it is clear that the main source for the European *theorica* tradition was Islamic *hay'a*; Ibn al-Haytham's *Configuration of the World* was certainly quite influential. In recent years, very strong similarities between the models and motivations of several Renaissance astronomers (including Copernicus) and the late *hay'a* tradition have been discovered, and it now seems quite likely that the former were influenced by Ṭūsī, Ibn al-Shāṭir, and other post twelfth-century writers on *hay'a*. However, because their works seem not to have been translated into Latin, the most likely means of transmission is through Byzantine sources that made their way to Italy (and perhaps Vienna) in the fifteenth century.

- March 8, 1756. His family were merchants and managed the Shichiya (bank) at Osaka.
- In 1795, the Shogun government planned to make a new calendar using Western astronomy. The former calendar, the Horeki calendar (1754), was a quite traditional Eastern Asian calendar, although Shogun Tokugawa Yoshimune (1684–1751, eighth Shogun, r. 1716–1745) wanted to use Western science. But there were no astronomers who had mastered Western astronomy in the Bakufu Tenmongata (Shogun's Astronomical Observatory). They asked ▶ Asada Goryu (1737–1799) to make a new calendar. However, Asada was already over 60 years old, so he recommended two students, Takahashi Yoshitoki (1764–1804) and Hazama Shigetomi.
- Takahashi was a *Doshin* (police officer) and a Samurai warrior. As Hazama was a merchant, Takahashi did the main work, and Hazama supported him financially. They worked in the Bakufu Tenmongata at Asakusa, Edo. Then Takahashi went to Kyoto to observe in 1796, and Hazama remained at Edo. They wrote the *Rekiho Shinsho* based on Kegler's (Part 2 of) *Li Suan Quan Shu* (1742, China, the same name as Mei's book) in 1797. They began using the Kansei calendar the next year.

Hazama Shigetomi

Shigeru Jochi

Osaka Kyoiku University (Osaka University of Education), Osaka, Japan

Hazama was a Japanese mathematician and astronomer in the Edo era. He was born at Osaka, the sixth son of Toichiya Gorobei, on

The healthcare scenario in urban India and globally is undergoing dramatic transformation, evolving into systems that emphasizes preventive health, customized care, body-mind medicine and the use of natural products. It is in this context that there has been in recent decades a resurgence of interest in the traditional Indian systems of medicine (ISM). The ISMs are based on the use of natural products. They view the human being and other life forms holistically in terms of both body and mind. They assess the uniqueness (*prakṛti*) of each individual and their universal principles can be tailored to the needs of every individual.

The transformation that is taking place in the healthcare scenario is reflected in the marketplace. The global market for herbal products is booming. The *Task Force Report of the Indian Planning Commission on Conservation and Sustainable Use of Medicinal Plants* (2000) estimated it to be about 62 billion per annum and rising at the rate of 15 % per annum. A large percentage of the population in Asia, Africa and South and Central America also depend on traditional knowledge and medicinal plants for their primary health care needs (WHO, 1993). This dependence is likely to continue, as rising costs of conventional healthcare make the traditional plant-based solutions the most viable, safe and affordable option.

Observers of the health sector believe that any societal model of healthcare based on a single system of medicine will soon become obsolete unless it broadens out to combine with complementary systems of medicine. The world's oldest codified and living systems of healthcare are Āyurveda, of Indian origin, and Traditional Chinese Medicine.

It is in the context of this growing consumption of traditional products that questions regarding quality standards have become a matter of concern to policy makers, consumers and to the regulatory authorities. Due to the difference in epistemologies, centuries of clinical evidence and practical methods for quality assurance that are available in the traditional ISM cannot automatically be transferred onto the parameters of western biomedicine, and such translations need to be supported by serious inter-cultural research and epistemologically sensitive methodology. An inter-cultural approach is inevitable because most herbal products originate from non-Western health sciences.

The English word "science" refers to a special kind of knowledge, which is clarified through reason and analysis. We find that our unclarified perceptions of the world are often too narrow, and that our assumptions and beliefs are all too often prejudiced. Accordingly, we use our scientific reason in two ways. On the one hand, we can put our narrow perceptions together, thus building them into broader pictures of the world. The world is thus described objectively,

by relating objects in conceptual pictures. Through systematic reasoning, these pictures grow into coherent fields of knowledge. Each field of knowledge has its own consistency, as a conceptual system, and each one has its place among the other fields.

On the other hand, in order to correct mistakes, our scientific reasoning can function in reverse. Instead of building pictures up, it can reflect back down, in order to investigate assumptions and beliefs. This reflective reason is essentially subjective. Its purpose is to educate, by asking questions that correct the questioner's own understanding. In Sanskrit, this corrective education is described by the word *śāstra*. Literally, "śāstra" means "correction" or "governance", but it is often used as a traditional word for science. It thus conceives of science as a correcting governance that is administered reflectively, through inward-turning reason.

These two ways of using reason have a long history of working together, since the beginnings of ancient science. But in the last few centuries, the objective way has prevailed. Unfortunately, the development has been one-sided. Our modern sciences have a tendency to emphasize the objective and calculating use of reason. So there has been a corresponding neglect of subjective education. It could well be argued that our current environmental crisis comes from this neglect of a more deeply reflective education, which is now needed to make better use of our specialized objective capabilities. The neglect has gone so far that the word "subjective" is routinely assumed to mean just "personal", and a subjective use of reason is thus put outside the essential and proper functioning of science.

Since science is essentially concerned with knowledge, it cannot be just personal. The problem is that our personal faculties are partial. They are partial faculties of body, sense and mind, which show us partial and differing appearances. No such appearance is entirely correct. Each bodily or sensual or mental appearance needs correction, to allow for different points of view. Therefore an impersonal standardization is essential to all sciences. But it can be approached in two ways, which are again objective and

subjective. The objective approach is directed externally, by prescribing standard techniques and instruments in the external world. The subjective approach is turned back in, through a reflective investigation of common principles that different people share, beneath the differing phenomena that nature manifests to them.

In the modern physical sciences that have developed in the last few centuries, the standardization is restrictedly objective. It requires that all theories are tested and applied through standardized instruments and machines, which we fabricate and use in the external world. Subjective reflection is specifically confined to the intuitive creation of ideas and theories. Once the theories are created, they must be tested and applied through their calculation of predicted results, which are measured and observed by a mechanical technology.

In older sciences, which have been developing for some thousands of years, more use is made of subjective reason. Here, reason works through education. Ideas are tested and applied in a living process of learning from experience, through common principles that underlie the variations of personality. The older sciences are based upon that inward investigation, towards a depth of knowing which is both subjective and impersonal. That depth of subjectivity is described by the Sanskrit words *ātma* and *ātmīya*.

The word “*ātma*” means “self”. It describes the self as a knowing subject at the inmost depth of personality, beneath the outward appearances of body, sense and mind. The word “*ātmīya*” means “subjective”. It refers to an inmost subjectivity, which is attained by reflecting back within. Here the word “subjective” is not being used to mean just “personal”. The self-called *ātma* is an inner principle of consciousness or spirit, and the word “*ātmīya*” thus means “spiritual”. It refers to a pure spirit that is found by inward detachment from outgoing personality. (The above discussion on science, vijñāna and on objective and subjective standards has borrowed from the unpublished article on Knowledge Before Printing and After of Ananda Wood, an eminent scholar and philosopher of science.)

Health Sciences in India: Traditional Health Sciences and Their Contemporary Application, Table 1 Two different knowledge systems

	Āyurveda, Indian health system	Biomedical science
Differing foundation	Based on nine existential entities: Earth (<i>pṛthivī</i>), Water (<i>ap</i>), Fire (<i>agni</i>), Air (<i>vāyu</i>), Space (<i>ākāśa</i>), Mind (<i>manas</i>), Time (<i>kāla</i>), Direction (<i>dik</i>), and the Soul (<i>ātman</i>)	Based on three existential entities: Matter, time and space
Differing worldview	Recognizes physical, biological and spiritual worlds <i>Sāṃkhya</i>	Recognizes physical and biological worlds Logical positivism and later schools
Differing logical system	Nyāya <i>Vaiśeṣika</i>	Aristotelian logic and its evolution
Differing categories	<i>Guṇa</i>	Phyto-chemistry and pharmacology
Differing pathogenesis	Loss of homeostasis	Infection via bacteria, parasite, virus

To place the above discussion in the specific context of healthcare, Table 1 gives a picture of the different epistemological foundations of western biomedicine and Āyurveda. It is important to appreciate these epistemological differences per se and not in terms of which is right or wrong or more superior or less. They represent different ways of knowing and viewing nature.

The traditional Indian systems of healthcare also have their own internal quality standards and logic for drug design and therapeutics. Table 2 illustrates the different logic of drug design and therapeutics used in Āyurveda.

Āyurveda is primarily based on the notion of “homeostasis”. This outlook is different from the theoretical approach of western medicine, which is largely based on disease causation due to infection, structural damages and systemic disorders whose etiology is poorly understood.

Health Sciences in India: Traditional Health Sciences and Their Contemporary Application, Table 2 Logic of Ayurvedic drug design

Logic of Ayurvedic drug design	
	
Therapeutic logic	
To break the chain of pathogenesis of a particular disease	
To alleviate specific symptoms of particular disease	
To block progression of the disease	
To reduce complication or associated diseases	
Pharmacological logic	
To select principal drugs and adjuvants having balanced therapeutic action	
To enhance bioavailability, spread and penetration, through appropriate dosage forms, time of administration, method and route of intake	
To design a combination of ingredients that does not cause unintended side effects	
Design for customization	
Drugs should suit Prakriti (genotype), age, customs, mental poise of the patient	
Drugs should suit local habitat and climate in which the patient resides	
Drugs should suit the digestive capacity (agni) and food habits of the patient	

Source: based on the *Carakasamhitā*

It is Āyurveda’s hypothesis that any disease, whether acute, chronic, degenerative, infectious or functional, occurs only when there is an internal imbalance or loss of equilibrium in the physiological or psychological functions of the body. The Āyurvedic treatments are designed to restore the specific kinds of imbalances caused by a particular disease. They are designed not only to resolve the immediate problem of the patient but also contribute to his/her sustained quality of health (*Āyushyam*). A drug is only one part of treatment. A holistic treatment also includes diet, non-drug therapies (like yoga and pancakarma) and life style changes.

In an emerging era of medical pluralism the project of developing modern inter-cultural standards for quality, safety and efficacy of traditional ISM is not only important for Indians but

also for global consumers. This article outlines the strategy for building upon traditional knowledge to create internationally acceptable modern quality standards.

Do Traditional Quality Standards Really Exist?

Any living, evolving system of traditional medicine which has served society for several millennia – such as we see in Asia, Africa and Latin America – could not have survived without possessing quality standards of its own. In most societies in these regions, health traditions remain undocumented because they are transmitted orally from generation to generation. This oral transmission, despite its remarkable

efficiency, outreach and cost-effectiveness, is poorly understood. There are also codified medical traditions with theory and clinical practice documented in the form of thousands of medical manuscripts in India and China.

In all traditional health cultures, quality standards do exist. They are expressed in the form of descriptions, advice and recommendations for identifying, collecting, processing and therapeutic use of natural products. The criteria for collecting plants, for instance, may include the best season and stage of growth for the plant to be most therapeutically active, and the best regions for gathering them in order to heighten their medicinal potency. There are also standards for storage, post-harvest, processing, and for finished products. Standards also exist for safety and efficacy.

In traditional societies, the health functionaries – the plant collectors, those who store the plants, and the physicians who prepare and administer the medicines – usually belonged to the same community as their customers. In earlier times the knowledge and integrity of the collectors and physicians served as an assurance of high standards. Today, the traditional quality standards can no longer be applied as those involved in preparing the medicines never meet their millions of customers face to face. Moreover, many more people are involved in the production and distribution chain. There is also a problem of soil, water and air pollution that can contaminate the raw materials.

The Inter-cultural Approach to Building Quality Standards

An inter-cultural approach involves the use of the modern scientific tools of physics, chemistry and biology to establish universally verifiable quality standards. The identification of the quality parameters that are to be standardized, however, does necessarily need to be based on the traditional knowledge systems from which the products are originally derived.

The evolution of inter-cultural standards is not an easy task as it assumes cross-cultural understanding and needs to engage experts in traditional knowledge and modern science in a

mutually respectful dialogue. This is not a short-term task; institutions for inter-cultural research need to be created. The starting point for creating quality standards is to establish the identity of the raw materials that go into the making of natural product. To identify the raw material (a plant, for instance), a reliable traditional source – texts as well as traditional knowledge holders – must be consulted. Tradition identifies materials by vernacular names and descriptions. It is necessary to link the vernacular names and descriptions of plants to the appropriate botanical entity. For example *Tulasi* is the vernacular name of a plant which when pointed out to a botanist would be correlated to *Ocimum sanctum*. In the case of certain vernacular names, however one vernacular name may correspond to more than one botanical entity. For example in the case of the plant referred to as *brahmi*, the Āyurvedic texts correlate this name to two distinct botanical entities *Baccoba monneri* (Neer brahmi) and *Centella asiatica* (Mandūkāparni) (Sastri, 1993). Other vernacular names like *pashan bheda* and *śankhapushpī* also have several botanical sources and acceptable regional substitutes, which are different species that possess similar pharmacological activity. There is another kind of complexity connected with vernacular names. This is the problem of synonymy wherein a single traditionally used plant entity may have as many as 70 vernacular synonyms, and one needs the help of traditional scholars to group all the vernacular synonymy that refers to a particular plant. This can be best illustrated by citing the case of a very important Āyurvedic text called the *Carakasamhitā*. In this text there are 12,000 plant names, but after resolving the problem of synonymy, these 12,000 vernacular names refer to only around 620 unique plant entities (Gopal, 2004). These are the kinds of problems that are involved in establishing the botanical identity of a vernacular plant name. It should be clear from the above that in order to establish the correct identity of a plant it is essential for botanists and traditional physicians to work very closely with each other because the inter-cultural correlation between vernacular names and botanical entities needs the intelligent involvement of both.

Since biological materials possess genotypic and phenotypic variability, while establishing standards in the case of a species with either a wide distribution range or even in the case of endemic populations, the sampling size should be adjusted to represent this diversity. For example *Phyllanthus emblica* is distributed right from the coastal plains to sub-tropical habitats and therefore standardizing such a material would require a statistically valid sampling strategy for this purpose.

The next stage in quality assurance of a raw material is to standardize collection procedures based on traditional recommendations regarding season, region and maturity of collection. And how it is processed and stored. Traditional medical texts under the topic *deśa vicara* specify the collection of raw materials at specific times of the plant's life cycle or advise collection from specific habitats. For example, the traditionally recommended mature tubers of the plant *Ipomea mauritiana* are richer in terms of both their bioactivity as well as in phytoconstituents than their immature counterparts (Venkatasubramanian, 2004). Another similar case involves the difference between the bioactivity of fresh and dry brahmi. Another example of collection standards is the case of Turmeric (*Curcuma longa* L.) whose rhizomes for therapeutic purposes are collected at nighttime. Preliminary studies indicate that bioactivity of turmeric collected at night was significantly different from that collected during the day. *Neem* (*Azardicta indica*) manifests its best therapeutic properties when collected from hot, dry and arid habitats (e.g. Rajasthan) than when it is collected from a high rainfall area (e.g. Kerala).

The more complex aspect of quality assurance arises in respect to the standardization of the finished product. Traditional products of different cultures use a wide range of processing techniques and also dosage forms, from simple powders made from a single plant, to extracts made from many plants. The finished products may be aqueous extracts, herbal wines, herbal oils, baked products, plant starches or alkalis. Standardizing all these myriad process and products poses a real

challenge to modern scientists. An interesting example of the relevance of traditional advice regarding processing can be seen in the case of an important pepper (*Piper longum*). This species is very widely used in Āyurveda. The extract of this plant in milk rather than water is better for therapeutic application. Bioassays indicate that the extract of the plant in milk is 27 times more active than the aqueous extract.

The Inter-cultural Gap in Pharmacopoeias

Today's Western-knowledge based pharmacopoeias – official handbooks on medical treatments – of traditional medicine like the US Pharmacopoeia, WHO monographs and even the Āyurvedic Pharmacopoeia of India, largely fail to adopt a comprehensive inter-cultural approach in setting quality standards. The quality standards they lay out for the drugs are limited to the presence of particular ingredients that are assumed to be active rather than the whole range of compounds that may be responsible for the drugs therapeutic actions. Most pharmacopoeias list aspects such as morphology, microscopy, physicochemical characteristics, nature of phytoconstituents and chromatography profiles, but are not as yet much informed by, or sensitive to collection protocols that are critical for the quality standards established by traditional health cultures. They are usually silent on the standards for several traditional dosage forms and online processes involved in their manufacture. This is partly because the information on traditional quality standards is not available in one place as a “ready reckoner” but mainly because an inter-cultural perspective is absent in their design.

International Regulations on Traditional Medicine

The biggest challenge lies in setting modern standards for evaluating a traditional drug's efficacy. This probably calls for a paradigm shift by designing a more holistic approach undertaking clinical trials. Most systems of traditional medicine adopt a multi-pronged approach to treatment. This involves drugs, diet and non-drug therapies. They aim at improving both mental

and physical well-being. Furthermore, the causes of disease and their classification in traditional systems of medicine do not have a one-to-one correlation with Western counterparts. Finally traditional treatments are designed to achieve homoeostasis, rather than to eliminate a single invasive agent.

These differences in the approaches to treatment give rise to two issues. The first is that unconventional evaluation protocols are needed to assess an entire treatment “package”, rather than one specific drug. The second is the need to use appropriate clinical, physiological, psychological or biochemical indices for evaluating outcomes which correlate well with the traditional understanding of cure.

In cases where differential diagnosis and treatment is indicated by TM for patients who from the western biomedicine perspective are suffering from the same disease, the conventional double-blind, placebo-controlled clinical trials might not always be necessary or appropriate. Case studies and observational studies – in which a clinical investigator monitors the effectiveness of treatment – can be valuable (Chaudhury & Chaudhury, 2002). Clinical trials need to be generally designed to evaluate a management regime, rather than a particular drug, although in the case of OTC drugs, the conventional design of drug trials is perhaps relevant.

In recent times regulatory authorities in importing countries such as Germany have restricted the role of traditional medicines to supplements that can be used only for “indications such as invigorating and strengthening” and which cannot be “intended to cure or treat disease” (Blumenthal, 1998). This is because investing in efficacy studies based on inter-culturally sensitive research models has not been recognized as an important enough area. In clinical research, most of the pharmacopoeial standards that are now available have been restricted to single plant extracts or at most extracts of five herbs as fixed combinations. This restrictive approach to the use of traditional medicine is depriving consumers round the world

of many of the benefits of several sophisticated poly-herbal traditional remedies.

With respect to safety, traditional remedies will need to be assessed within the same parameters now used for modern pharmaceutical, nutraceutical and cosmeceutical products. The WHO has accepted that traditional medicines may need less rigorous preclinical toxicological evaluations since their safety of use has been documented historically (Venkatasubramanian, 2004). However in the case of traditional products that are based on the use of metals and minerals, whereas they are known to be therapeutically potent, it is extremely important to ensure that the traditionally prescribed processes are rigorously adhered to else the products can result in toxic side effects. In fact the traditional pharmacy texts themselves underline the need for such rigor. For example in the case of *bhasmas* the particle size of the finished products is expected to be smaller than the intra-cellular space and the products should no longer carry any trace of the metal in its original form. Modern tools like the electron microscope and atomic absorption spectrometer can aid in the evaluation of such products.

The latest EU regulations on traditional medicine state that traditional products must be safe and meet prescribed standards of quality if they have been used for at least 30 years. A catch in this legislation is that 15 years had to be within the European Community itself (Chaudhury & Chaudhury, 2002). This is in principle a progressive rule because it recognizes the value of traditional knowledge. Its practice however needs to be worked out in a way that is fair and makes best use of traditional medical cultures that are located outside the European Union.

Policymakers and medical researchers should understand that the evaluation of traditional systems of medicine and their inherent standards involves inter-cultural research. This is a vital pursuit, as it can enrich the field of medical pluralism – which in its turn seems to be the best route towards the advancement of world medicine.

Holography

Jehane Ragai

The American University in Cairo, Cairo, Egypt

Appearance and Reality

This entry attempts to show that an ancient period of human creativity as expressed in Egyptian art has an analog in the twentieth-century discovery of holography. Parallels are perceived between both the “frontal-profile stance” and the “canonical tradition” of Egyptian art and the model of the hologram. These analogies appear on both the “empirical” and “conceptual levels” (It is to be noted that an earlier version of this entry appeared in 1986 both in English and in French, in *Aujourd’hui l’Egypte*. Permission to reproduce an updated version was granted to the author by

the editor of *Aujourd’hui l’Egypte*: Mr. Jean Chamas).

Recent breakthroughs in modern physics (Capra, 1980; Jones, 1983; Zuhav, 1980) have drawn attention to the innumerable parallels between the new ways of interpreting modern physics and Eastern mysticism. Capra (1980) in his *Tao of Physics* reflects this trend when he observes:

...The basic elements of the Eastern world view are also those of the world view emerging from modern physics... Eastern thought provides a consistent and relevant philosophical background to the theories of contemporary science...

Similar to modern physics, holograms also lead to a world view which is essentially mystical (Bohm, 1980). The roots of such a view can be found in an earlier period of human creativity, that of Ancient Egypt, where the belief in the mystical reality of art gave impetus to the unparalleled artistic productivity of its people. Through the examination of the frontal-profile stance and the canon, we will demonstrate how the hologram and Ancient Egyptian works of art, which at first glance may seem totally unrelated, share many common features. The entry concludes by suggesting that these two complementary manifestations of the human mind are united in their mystical view of the world.

It is hoped that the ideas expressed in this paper will prove relevant in showing that there is an essential harmony and complementarity between the humanities and science leading to a better understanding of the world around us.

Frontal-Profile Stance in Ancient Egyptian Art

To the Ancient Egyptians an intimate relationship existed between art and the fundamental belief of how to live and die. Where an obsessive horror of death and extinction was reconciled with an absolute faith in immortality, art played an active role.

The Egyptian artist was concerned not with representing a fleeting impression captured transiently, but with what he regarded as an

individual's personal eternity. Principal figures were shown at an undefined age, conforming to preconceived standards of bodily health and vigor. Individual features showed little variation and personal traits were generally avoided. Figures in general were not intended as portraits of the deceased but "...symbolic representations of a perfect man and his family..." (David, 1975) a representation of what was expected to exist for perpetuity.

Each individual object had therefore to be represented in its entirety, as a "whole," with no parts hidden or distorted by shifts of perspective, "because parts omitted were considered missing and bound to mar the eternal image of the objects they represented" (Iversen, 1975).

This led to one of the fundamental features of Ancient Egyptian art: the principle of "frontal images" or the "aspective" (Shafer, 1974) as opposed to the "perspective" approach.

Egyptian artists selected in their two-dimensional renderings, only those possibilities which were free from the illusion of perspective, in which characteristic individual parts of an object were set unforeshortened almost as a series of juxtaposed phases.

Applied to human figures, this "frontal-profile" aspect was expressed in an extraordinary treatment of the human body. Apart from rare instances the head and the neck were invariably represented in profile yet the eye was presented full face (Fig. 1). The torso was turned square to the spectator with the nipple seen in profile and the navel "en face." Legs and feet were represented in profile with the left leg foremost (Fig. 1).

Such an impossible physical contortion avoided the perspectival solution to the problem. Through the integration of the front and side views, Ancient Egyptians thus managed to achieve a three-dimensional representation of objects on a plane surface.

It is in this "aspective" expression of Egyptian art, where each element of the representation was scrupulously reproduced, that a first analogy may be perceived with modern holography. To clarify this point and demonstrate the parallels, a few

Holography, Fig. 1 The Ancient Egyptian canon of proportions

words of explanation about holograms are in order.

Holography is a method of lenseless photography in which the wave field of light scattered by an object is recorded as an interference pattern. When the photographic record called a "hologram" is placed in a light beam, the original pattern is regenerated and the observer sees a three-dimensional picture that is an amazingly realistic image of the original object.

If one moves one's head, one can see a top, bottom, and side view, just as if the object actually existed in space before one's eyes.

To make a hologram, one starts with a single monochromatic and coherent beam of light from a very small source:

...This single beam is then split into two components, one of which is directed towards the object, the other is directed to a suitable recording medium, usually a photographic emulsion. The component beam that is directed to the object is scattered, or diffracted by that object. The wave

Holography, Fig. 2 Creating a hologram

that proceeds directly to the recording beam is termed the “reference beam”. Since the object and reference waves are mutually coherent, they will form a stable interference pattern when they meet at the recording medium. . . the detailed permanent record of this interference pattern on the photographic emulsion, which we call the “hologram” consists of a complex distribution of clear and opaque areas corresponding to the recorded interference fringes. When this in turn is illuminated with a beam of light which is similar to the original reference wave, light will only be transmitted through the clear areas, resulting in a complex transmitted wave. The latter conveniently divides into three separate components, one of which exactly duplicates the original object wave. Thus “holography” is a two-step process by which images can be formed.

In the first step a complex interference pattern is recorded and becomes the hologram. In the second step, the hologram is illuminated in such a way that part of the transmitted light is an exact replica of the original object wave (Smith, 1975) (Fig. 2).

The concept of three-dimensional realism with only two in use is therefore encountered in both Ancient Egyptian art and modern holography.

Such a parallel becomes even more evident by considering De Rachewiltz’s (1960) description of Ancient Egyptian two-dimensional representations:

...on a flat surface (space) an image is drawn which at the same moment (time) evokes a plurality of individual visions. It is almost as if the figure were visualised from several sides, seen simultaneously in profile and from the front in its essential “reality” which is derived from one vision of the various sides synthesized on the flat surface.

Canons as Holograms

Another striking feature of Egyptian Art, both in the sculpture and in the painting, is the serenity and immutability of the people and the scenes.

A sense of inner life and power imbued with calmness emanates from the various art works. The representation of the human figures suggests that the Egyptian artist’s aim was to establish for all times the laws of harmony and perfection. Such harmony was expressed in idealized human figures free from physical defects and enjoying the blessings of life (Fig. 3).

Technically, such standards of beauty were reached by making use of the well-known “artistic canon.” The latter was encountered in Ancient Egyptian art since the beginning of the dynastic times and represents a system of proportions which was used to indicate the mutual relations of the different parts of the body in its artistic representation. According to Iversen (1975) and Harris (1971), the problem faced by the Egyptians of how to scale the various parts of the body was solved by resorting to an accurate standardization of the natural proportions of the body.

His arguments were based on the premise that within distinct types and ethnic groups, the relations of the various parts of the human body are constant and immutable in all individuals, irrespective of any differences in size and dimensions.

Holography, Fig. 3 Triad of King Menkaure (Picture taken by Dr. John Swanson and reproduced through his permission and that of the director of the Cairo museum Dr. Wafaa al Sadek)

Recent investigations (Robins & Miszellen, 1976) have, however, indicated that Egyptians gave their figures idealized proportions which reflected certain standards of beauty and were not necessarily totally in correspondence with the natural proportions of the body.

Here we are reminded of Plato (1963), according to whom "...Egyptian artists abandoned the truth and gave their figures not the actual proportions but that which they considered beautiful. ..." Whether or not such was the case, there definitely existed a standardized relation between the various parts of the represented figures, and these were based on anthropometric measurements.

For the practical application of such a system, the Egyptians invented the so-called grids, a system of squares in which the width of the grid square was taken as a rough guide for the width of the fist:

On the rectangular blocks intended for sculpture in the round, the squares were drawn or incised on at

least two sides, and on the plane surfaces prepared for two-dimensional representations, they were either ruled with a straight edge or marked by means of strings dipped in red ochre. (Robins & Miszellen, 1984)

A canon of proportions thus evolved as early as the Old Kingdom (3200–2280 BCE), and from the Middle Kingdom (1991–1786 BCE) onwards, it became a normal practice to relate the parts of the body to a grid consisting of 18 squares from the soles to the hairline (Robins & Miszellen, 1983, Fig. 1).

Such a "classical" grid was from the 26th Dynasty (664 BCE), replaced by the "late" grid, known as the "Saite Canon," dividing the height of the male figure into 21 squares from the sole to a new measuring point at the root of the nose.

Without changing the mutual relations of the parts, the dimensions of all proportions of any figure could be altered indefinitely by the simple process of changing the length of the modular square ($1/18$ or $1/21$ of the height depending on what canon was used).

Egyptian artists were therefore able, for more than two millennia, "to find a complete harmonious expression within a single tradition, without once changing its principles and ideas - with the sole exception of the Amarna age" (Harris, 1971).

Robins and Miszellen (1983) recently showed that during the latter period a canon of proportions based on 20 squares from the sole to the hairline was introduced.

It is in this canonical tradition of Ancient Egyptian art that a further analogy may be perceived with modern holography. To appreciate such a similarity, let me point out another crucial property of holograms.

In holography the light scattered from each point of the object spreads out as to cover the entire photographic plate. This means that there is no longer a one-to-one correspondence between a portion of the hologram and a region of the object. The information of any single point is recorded over the "whole" plate.

Because of this only a small portion of the hologram is required to form an image of the whole object (Butters, 1971; Develis & Reynolds, 1967; Smith, 1975). If the hologram were

to be shattered into thousands of splinters of glass, it would still be possible to form, on any small particle of glass, the entire representation.

This key new feature which is apparent in holography that of an unbroken wholeness, where each part contains information about the entire object, is also apparent in the Ancient Egyptian canon of proportions. Any small part of the artistic figure gives, through its dimensions, information of the whole.

The following argument will also show that just as in a hologram, the representation is “everywhere” in the glass plate, shot through it; the communication or message conveyed by the canon is contained everywhere in the work of art (Ross, 1982).

The observation of Egyptian representations as well as a detailed reading of published work (Aldred, 1980; David, 1975; Davies, 1982; De Rachewiltz, 1960; Harris, 1971; Iversen, 1975; Kielland, 1955; Plato, 1963; Robins & Mizzellen, 1976, 1983, 1984; Romano & Bothmer, 1958; Ross, 1982; Shafer, 1974; Smith, 1975; Steindorff, 1949) on Ancient Egyptian art convinces us that through the symbols and metaphors embodied by the canon, a “mystical” message is conveyed that is highly consonant with modern physics (Capra, 1980; Zukhav, 1980). Such a message incorporates the ideas of the interrelatedness of all things, the transcendence of the notion of an individual self-coupled with the firm belief that all observations are but manifestations of the same ultimate reality and finally the idea that space and time are constructs of the mind.

That all things and events perceived by the senses are interrelated and connected is, by virtue of the canon, metaphorically suggested throughout the Ancient Egyptian work of art. The standardized relation between the various parts of the figures such as the relation of thumbs to fingers, fingers to palm, palm to forearm, and forearm to height and breadth symbolically confirms this interdependence. All things are seen as inseparable parts of this cosmic whole.

The canonical tradition, by allowing the tomb owner and his family to be represented as idealized humans with slender bodies and youthful beauty free from physical defects and devoid of

individual and personal traits, expresses a transition from differentiation to sameness. What appears to be different finally is seen to be the same. The canon, throughout the art work, allows the individuality to be dissolved into an undifferentiated oneness where the notion of an individual self is transcended leading to an identification with the same ultimate reality (Figs. 3 and 5).

Iversen (1975), referring to the lack of specification of Ancient Egyptian works of art in the spatiotemporal plane, writes:

In order to prevent any temporal aspect to influence the existence of the individual representations the indications of any particular moment in their corruptible state was studiously avoided. . .

Ancient Egyptian works of art, created out of their spatiotemporal appearances, suggest that space and time are constructs of the mind. Such a message can be shown to be “hologrammed” by the canon.

Indeed a close observation of Ancient Egyptian figures suggests that each single part in the Ancient Egyptian work of art is given a form that is appropriate to its meaning, conveying to the figure as a whole a message valid for eternity.

Starting with the representation of the “feet” (Fig. 1), it is observed that the arch which is generally closed on the outside is shown to appear from the exterior; also “legs” are in most cases depicted as being a pace apart, even when surrounded by seated or kneeling people. Observation of Fig. 1 also suggests that the “hand” hanging open behind the back is mostly so placed that the thumb is turned away from the body. Shafer (1974), commenting on the position of the hands, makes the following conclusions:

. . . This strange positioning of the hands poses great problems as long as the human figure is taken to be the rendering of a single real view. But it does the artist an injustice to consider his work in this way. . .

The intermingling in these representations of the concepts of “back” and “front,” “inner” and “outer,” and those of “rest” and “movement” indeed does suggest an arrest in time and space.

Holography, Fig. 4 Queen Nefertari

In their depiction of “parts” as well as of the “whole” in figures, Egyptian artists were thus inclined not to follow their visual impressions. Instead they sought to convey the significance of a subject by portraying it in an abstract manner, outside space and time (Fig. 4).

It is also noteworthy that in these artistic renderings facial representations were generally devoid of all signs of emotion and of details specifying human feelings and passions (Fig. 5).

The images had a tone of extreme dignity, almost of a higher existence which has been achieved and of which the subject was completely aware. Here, once more, we become aware of artistic expressions taken out of their ephemeral temporal representations.

It becomes clear that the adaptation of the artistic production to a “canon,” considered as an expression of the divine law of harmony, has allowed the full expression of an unbroken

Holography, Fig. 5 Tuthmosis III (Picture taken by the late Dr. Bernard Bothmer) (Reproduced by permission of Mrs. Bothmer and Mrs. Sanaa Ahmed Ali (director of the Luxor museum))

wholeness through which is “hologrammed” a highly mystical message. The artist fashioned an image that expresses in generalized terms the nature of “man” as such.

His prime concern is to create not a likeness but first and foremost “a symbol.”

Conclusion

This entry has attempted to link an ancient period of human creativity, as expressed in Egyptian art, with a modern twentieth-century discovery: holography. Ancient Egyptian works of art and holograms are seen to have striking parallels both on an “empirical” and on a “conceptual” level.

Both techniques, in spite of their different approaches, have succeeded in achieving a mapping of three dimensions onto two. Ancient Egyptian artists did not base their

representations on perspective but were rather concerned to communicate all of the details of the figure by giving every vital part its full definition. If the head were shown frontally, the definition of the nose would be lost for eternity. Similarly the eye and torso had to be exhibited in their most characteristic light and were therefore shown frontally legs and feet which would have been foreshortened if shown frontally were indicated in profile. Such an approach thus gave the “complete” information about the represented figure.

Similarly, holography by reproducing an exact replica of the original object provided an illusion of three-dimensional concreteness from which could be extracted the “whole” information relating to the object.

An additional property, common to both holograms and Ancient Egyptian works of art and also evident on an empirical level, is that just as in a hologram any fragment, which is very small, gives information on the whole object, and in Ancient Egyptian works of art by virtue of the canon, any part of the figure allows the computation of the dimensions of the other parts and of the whole.

From a conceptual point of view, both holograms and Ancient Egyptian works of art similar to modern physics lead to an essentially mystical world view.

Thus, as observed by Bohm (1980):

Holograms provide an immediate perceptual insight into what is meant by undivided wholeness in which the classical idea of the analyzability of the world into separately and independently existing parts is denied.

In an analogous manner Ancient Egyptian art works are “. . . created as a UNITY in which every detail and measurement is determined in relation to the whole. . .” (Kielland, 1955). The interdependence and interconnectedness of all things are again made evident here.

This highly mystical approach is not only conveyed by considering the Ancient Egyptian art work in its entirety but is also seen to be “hologrammed” throughout the individual parts.

As Plato suggests:

The Egyptians managed to penetrate a reality beyond the “merely” seeming presenting this comprehensive intuition in artistic form, as a vision of underlying order in the universe. (Davies, 1982; Plato, 1963)

In the same line of thought, we may reflect on Bohm’s suggestions that the “universe itself may be a hologram,” a realm of frequencies and potentialities underlying an illusion of concreteness, or what he calls the “enfolding” order.

What we actually “see” is the “unfolded” order giving recognizable images of “whole” objects (Bohm, 1980; Milbourn unpublished). Bohm suggests that our reality is of objects rather than waves “because our senses are lens systems” (Fig. 2):

If the universal reality is based on the holographic principle, then what is needed to tune into this reality is a means of bypassing the lens system of the senses and experience the waves of the enfolding order directly. (Milbourn unpublished)

We are reminded here of Steindorff’s (1949) description of Egyptian non-perspectival art as an art “that concerns itself with the object not as it appears to the eye, but as it exists in the imagination of the artist,” representing a mental image that transcends the world of senses.

Thus, both Ancient Egyptian works of art and holograms may be conceived as resulting from an awareness raised to a level above the brain’s sensory input, in which the different aspects of nature, whether recorded as an interference pattern of scattered light or whether resulting from what may be termed the “holographic activity” of the Ancient Egyptian brain, have led to a blurring of the demarcation line between “appearance” and “reality.”

Acknowledgments I would like to thank the late Dr. Bernard Bothmer, Professor of Egyptian Art (Institute of Fine Arts, New York University), for his encouragement, his useful comments, and his assistance in providing resources unattainable in Egypt, when this entry was first written. I also thank the late Dr. Cynthia Nelson, Professor of Anthropology (the American University in Cairo), for her insightful comments which have improved the quality of this text. I would also like to thank the late Dr. S. J. Gregg, formerly of the department

of Chemistry (the University of Exeter), for his unfailing encouragement. Last but not least, grateful thanks go to Dr. Wafaa al Sadek, Mrs. Sanaa Ahmed Ali, Mrs. Bernard Bothmer, and Dr. John Swanson for their permission to use some of the present pictures.

Honey and Medicine

Rachel Hajar

There is evidence that man has long known that honey is a valuable food source. Early rock paintings on cave walls in Africa and eastern Spain show people gathering honey from trees or rock crevices while bees fly around them (Crane, 1999). A rock painting called the “Man of Bicorp” shown in Fig. 1 was discovered in 1921 in the *Cueva de la Arana* (Spider Cave) in Valencia, Spain. The painting depicts a human figure near a cavity where there is a beehive. Hanging on three lianas, he is picking up honeycombs, while nearby are some stylized bees. The painting is believed to be over 15,000 years old and dates back to the end of the Paleolithic Period. Rock art

Honey and Medicine, Fig. 1 “Man of Bicorp” ca. 15000 B.C.E. Paleolithic rock painting showing honey collection from a wild nest, Cueva de la Arana, Bicorp, Valencia, Spain (Drawing E. Hernandez-Pacheco). <http://www.rupestre.net/tracce/bicorp.html>

from other caves has been found, which shows figures surrounded by bees without being stung.

Prehistoric honey gatherers probably learned by accident that bees are driven away from the honeycomb by smoke as an offshoot of using fire for “warding-off” or driving other animals. Most likely early humans observed the habits of bees and learned that wild bees made their home in the hollow limbs of trees or in hollow places in the trunks of trees. Even now, bee trees often can be found by walking through the woods on bright sunny days and looking into the tops of the trees and watching for the bees coming and going.

The “Man of Bicorp” cave painting is clear proof that early humans actively sought honey as part of their diet. We do not know, however, whether prehistoric man used honey for medicinal purposes.

Honey hunting is an ancient tradition that is still practiced in isolated cultures in Africa, the Indian subcontinent, Southeast Asia, Australia, and South America. Reports of such activities in the popular press describe the practice as heavily permeated with ritual. This is not surprising since the tradition was passed down for generations and has its origins from our distant past.

Honey hunting is a dangerous pursuit since a bee sting could be fatal. Throughout history, there have been alternatives to honey as a sweetener, such as dates and figs. Yet, humans seem to prefer honey and one wonders why humans like honey so much.

Honey in Mythology and Religion

The widespread perception that honey is “good” has its genesis from folklore. Myth has played an important role in folklore. Oral and written records abound with the life-giving qualities of honey.

Quantitative studies of hunter-gatherer diets are scarce. The *Veddas*, or Wild Men, of Sri Lanka esteem honey so highly that they regularly risk their lives to obtain it. The results of a study among some Australian aboriginal tribes reveal that wild honey is regularly consumed although it is difficult and challenging to obtain.

Unfortunately, research into the nutritional role of honey is scanty. However, studies of primitive tribal diets indicate that honey is highly nutritious. For example, among the Guayaki Indians of Paraguay honey is the very basis of their diet and culture (Fallon & Enig, 1999).

Mythology offers rich insights into the perceived life-sustaining qualities of honey. In Greek mythology, Zeus, mightiest of the Greek gods, was hidden from his father who wanted to devour him and was raised on honey and milk by the bee-nymph, Melisseas. Honey made him so strong and tough that when he grew up he seized his father’s throne.

Another myth is that *ambrosia* was the food of the gods and goddesses. Since their gods’ food consisted only of ambrosia, the ancient Greeks attributed the immortality of their gods to ambrosia, which they believed consisted of honey, milk, and nectar. Ambrosia was thought to be a nine-fold extract of honey – a sweet treat enjoyed by mortals throughout the ages. Honey was a divine symbol for the Greeks and honey mixed with blood was the sweetest oblation.

Besides its nutritious benefits, the ancients may have believed that honey had properties to preserve or enhance beauty. It is claimed that many of Cleopatra’s cosmetics were honey-based. Many women in Arabia still believe honey softens their skin and regularly apply it as facial mask.

In Egyptian mythology, “when the God Re wept, his tears fell to the ground and were turned into bees. The bees began to build and were active on all flowers of every kind belonging to the plant kingdom. Thus wax came into being, thus was created honey from the tears of the God Re” (Ancient Egyptian beekeeping).

The ancient Egyptians offered their gods honeycombs overflowing with honey as a valuable gift to show devotion and worship. In the twelfth century B.C.E., Ramses III offered 15 tons of honey to Hapi, the god of the Nile. Jars of honey were buried with the dead as sustenance for the afterlife. Archaeologists have found clay pots filled with honey in a Pharaoh’s tomb in the city of Thebes. The inscription on the clay pot read: *Good Quality Honey*. Large quantities of

honey in jars were also found in the tomb of Tutankhamen (Salim, 1988). Burying the dead (especially nobility) in or with honey was common practice in Egypt, Mesopotamia [Iraq], and other regions. It is rumored that Alexander the Great was buried in honey.

The Pharaohs also used honey in their wedding celebrations. This custom was passed on to Greco-Roman culture and handed down to Medieval Europe. Newlyweds drank honey wine (mead) for a month after the wedding ceremony for good luck and happiness. The ritual gave rise to the word *honeymoon*. Egyptian hieroglyphics dating back at least 3,000 years indicate that honey was used as the principal sweetener in the Egyptian diet and as a base for medicinal unguents. The Egyptians also collected beeswax for use in molding wax images for metal casting and in the “varnishing” of pigments (Shaw & Nicholson, 1995).

The first written record of beekeeping can be traced back to Egypt from about 2400 B.C.E. Figure 2 depicts a relief of hives in ancient Egypt, which are very much similar to the woven wicker baskets covered with clay that are still used in Sudan today.

Temples kept bees in order to satisfy the demand for honey as offerings to the gods as well as for other domestic uses such as mummifying, boat, and ship building, and as a binding agent for paints and in metal casting. However,

the Egyptians valued wild honey more than the homegrown variety. A passage from the Papyrus Harris reads, “I appointed for thee archers and collectors of honey, bearing incense to deliver their yearly impost into thy august treasury” (Breasted, 1906).

Honey is frequently mentioned in the Bible. Moses led his people to the “land of milk and honey.” Solomon in Proverbs 24:13 advised, “My son, eat honey; it is good. And just as honey from the comb is sweet on your tongue, you may be sure that wisdom is good for the soul. Get wisdom and have a bright future.” The Jews believed honey made a person “mentally keen.”

In early Christianity, honey had a deep mysterious meaning and it was given in christening ceremonies as a symbol of renovation and spiritual perfection. When St. John, the Baptist, was in the desert, he lived on honey and locusts. Bees were revered because of their ability to produce wax and therefore provide light, in many cases for religious practices. Before the advent of electricity, candles were important for lighting. In many religions, candles are still used for religious ceremonies. The Roman Catholic Church regarded the bee as an example of godliness and believed beeswax to be “pure” since virgins – i.e., nonmating worker bees – produce it. Monks kept bees to provide beeswax to make candles for the church.

Honey as Medicine in History

It is possible that prehistoric human's experiences with honey as a valuable food source became encoded in our mythology. In time, the mythic belief that honey was the "food of the gods" passed into ancient writings. Since it was the food of the gods, it must contain the ingredient of immortality, fostering the perception that honey contains the secret to a long and healthy life. It was prescribed as panacea for various ailments and diseases.

Healing for Mankind

"Thy Lord taught the Bee to build its cells in hills, on trees and in man's habitations; Then to eat of all the produce of the earth. . . From within their bodies comes a drink of varying colors, wherein is healing for mankind." (*Qur'ān*, Surah XVI: 68–69). The prophet Muḥammad advised his followers to "Use the two curatives: honey and Qur'ān."

Likewise, the Bible contains many references to honey. "But Jonathan [son of Saul]. . . reached out the end of the staff that was in his hand and dipped it into the honeycomb. He raised his hand to his mouth, and his eyes brightened." (1 Samuel 14:24).

The Hindu Vedas, composed about 1500 B.C.E. and written down about 600 B.C.E.,

speak of "this herb, born of honey, dripping honey, sweet honey, honied, is the remedy for injuries; moreover it crushes insects." In the section on *Hymn To All Magic And Medicinal Plants*, honey is used as a universal remedy: "The plants. . . which remove disease, are full of blossoms, and rich in honey" (Blomfield, 1973).

All the sacred books, including those of China, praise honey as food, beverage, and medicine (Jones, 2001).

Ancient Writings

There are abundant references to honey as medicine in ancient scrolls, tablets, and books. It was prescribed for a variety of illnesses. Excavated medical tablets from Mesopotamia indicate that honey was a common ingredient in many prescriptions. In ancient Egyptian medicine, honey was the most frequent ingredient in all the drug recipes for both internal and external uses listed in the Ebers and Edwin Smith Papyri (Estes, 1993). Honey was used for treatment of stomach pain, urinary retention, and as an ointment for dry skin. It was used for wounds and burns, skin irritation, and eye diseases.

The author of the Smith Papyrus shown in Fig. 3 directed that honey be applied topically, with few if any other possibly active ingredients, to wounds. An example appears below:

Honey and Medicine,

Fig. 3 Excerpt from the Edwin Smith Papyrus (Illustration taken from Ancient Egypt. The Edwin Smith Surgical Papyrus. <http://nefertiti.iwebland.com/timelines/topics/smithpapyrus.htm>)

Instructions Concerning A Wound In His Head, Penetrating To The Bone:

If thou examinest a man having a gaping wound in his head, penetrating to the bone, thou should'st lay thy hand upon it (and) thou should'st palpate his wound. If thou findest his skull uninjured, not having a perforation in it. . .

Thou shouldst bind fresh meat upon it the first day, thou shouldst apply two strips of linen; and treat afterward with grease, honey, (and) lint every day until he recovers.

In ancient Egypt, honey was the only active ingredient in an ointment described in the Ebers Papyrus for application to the surgical wound of circumcision. Ebers also specifies that an ointment for the ear be made of one-third honey and two-thirds oil. The concentration of honey in seven oral remedies in the Chester Beatty VI Papyrus ranges from 10 % to 50 %, while its proportion in other remedies ranges from 20 % to 84 %. Honey could very well have provided some kind of protection from the kinds of bacteria most likely to infect wounds, at least enough protection to permit wounds to begin healing on their own.

The ancient Egyptians were not the only people who used honey as medicine. The Chinese, Indians, ancient Greeks, Romans, and Arabs used honey in combination with other herbs and on its own, to treat wounds and various other diseases.

Aristotle (384–322 B.C.E.) believed that eating honey prolonged life (Jones, 2001). Dioscorides (A.D. 40–90), a Greek physician who traveled as a surgeon with the armies of the Roman emperor Nero, compiled *De Materia Medica* (shown in Fig. 4) around A.D. 77. *De Materia Medica* was the foremost classical source of modern botanical terminology and the leading European pharmacological text until the fifteenth century.

In addition to excellent descriptions of nearly 600 plants and 1,000 simple drugs, Dioscorides described the medicinal and dietetic value of animal derivatives such as milk and honey. Dioscorides stated that honey could be used as treatment for stomach disease, a wound that has pus, hemorrhoids, and to stop coughing (Salim, 1988).

Honey and Medicine, Fig. 4 (a) Dioscorides, *De Materia Medica*, 15th c. Iviron Monastery, Mount Athos, Greece (18.25 Dioscorides, *De Materia Medica* (Books I-V) 15th c. Iviron Monastery, Cod. 216 Illustration from <http://www.culture.gr/2/21/218/218er/>

Honey opens the blood vessels and attracts moisture. If cooked and applied to fresh wounds it seals them. It is good for deep dirty wounds. Honey mixed with salt could be dropped inside a painful ear. It will reduce the pain and swelling of the ear. It will kill lice if infested children's skin is painted with it. It may also improve vision. Gargle with honey to reduce tonsil swelling. For coughing, drink warm honey and mix with rose oil (Dioscorides 65 A.D.).

A tenth century Arab philosopher mentioned uncooked honey for swollen intestines whereas cooked honey was good to induce vomiting when a poisonous drug had been ingested. Al Rāzī (Rhazes, A.D. 864–932), a renowned Muslim physician famous for writing a treatise distinguishing measles from smallpox, claimed that honey ointment made of flour and honey vinegar was good for skin disease and sports nerve injuries, and recommended the use of honey water for bladder wounds (Salim, 1988). His book, *Al Hāwī* (Encyclopedia of Medicine), a comprehensive medical textbook of medicine, which was translated from Arabic to Latin in the thirteenth century and became a standard textbook of medicine up to the 1700s stated:

Honey is the best treatment for the gums. To keep the teeth healthy mix honey with vinegar and use as mouth wash daily. If you rub the teeth with such a preparation it will whiten the teeth. Honey does not spoil and could also be used to preserve cadavers.

► **Ibn Sīnā (Avicenna)**, another famous Muslim physician whose great medical treatise, the *Canon*, was the standard textbook on medicine in the Arab world and Europe until the seventeenth century, wrote:

Honey is good for prolonging life, preserving activity in old age. If you want to keep your youth, take honey. If you are above the age of 45, eat honey regularly, especially mixed with chestnut powder. Honey and flour could be used as dressing for wounds. For lung disease, early stage of tuberculosis, use a combination of honey and shredded rose petals. Honey can be used for insomnia on occasions.

Throughout the ages, honey was prescribed for a variety of uses, frequently mixed with herbs, grains, and other botanicals. Remedies were passed down through the millennia because they seemed to be effective. Many ancient remedies survive today, lumped together by modern medicine under the term “folk medicine” since their effectiveness has not been scientifically proven through clinical trials.

The belief in honey as a remedy for ailments is still pervasive. Honey for coughs and sore throats remains a popular remedy around the world. Honey is frequently mixed with tea and cinnamon as remedy for cold and sore throat. Some antiseptic lozenges contain honey.

In underdeveloped countries, where synthetic medicines are expensive, honey is one of the cornerstones in their pharmacopoeia. For example, lotus honey is used for eye diseases in India. It is used as topical eye ointment in measles to prevent corneal scarring (Molan, 2001). Honey is used to treat infected leg ulcers in Ghana and earaches in Nigeria. Other uses include treatment of gastric ulcers and constipation (Getz, 1991).

Honey in the Twentieth Century Before Antibiotics

In the early part of the twentieth century, the medical literature contained reports on the antimicrobial and healing properties of honey. Russian soldiers during World War I used honey to prevent infections in wounds and to accelerate healing (Bergman, Janai, Weiss et al., 1983). The effectiveness of honey to heal wounds spurred research into its antimicrobial activity, which was attributed to “inhibine.” In 1963, inhibine was identified as hydrogen peroxide (White, Subers, & Schepartz, 1963), a powerful oxidizer that kills bacteria, viruses, and fungi. During the first half of the twentieth century, there were many research papers documenting the wound-healing properties of honey. The

medical profession did acknowledge the value of honey in the treatment of wounds, leg ulcers, and burns. The introduction of antibiotics shifted the focus to synthetic and mass-produced treatment. The medical uses of honey as effective treatment in wounds were forgotten.

Revival of Honey in Medicine

In 1976, an editorial in the *Archives of Internal Medicine* on medical folklore arrogantly dismissed honey as a “worthless but harmless substance” (Soffer, 1976). Over the last two decades, reports from different parts of the world affirmed the effectiveness of honey in treating various wounds, burns, and serious infections. These reports and the emergence of drug resistant infections stimulated a number of scientists to conduct studies on honey, bringing about a resurgence of interest in the medical uses of honey. Recent research on honey has shed light on the mechanisms underlying its antimicrobial effects (Molan, 1992). In summary, the antibacterial effects are due to

that are not hydrogen peroxide but their concentration is reportedly too low to contribute much antibacterial activity.

Honey has been reported to have an inhibitory effect to around 60 species of bacteria including aerobes and anaerobes, gram-positives and gram-negatives (Subrahmanyam, 1991).

There are differences in the antibacterial activity of different honeys. Honey is produced from many different floral sources and its antibacterial activity varies with origin and processing. Long ago, both Aristotle and Dioscorides recommended that honey collected in specific regions and seasons, and presumably from different floral sources, be used for the treatment of particular ailments. Research has since shown that honey has certain organisms sensitive to it while others are resistant, and the sensitivity varies depending on the source of the honey. *Staphylococcus aureus* is one of the species most sensitive to the antibacterial activity of honey (Cooper, Molan, & Harding, 2002).

Other beneficial effects of honey include (Molan, 1992):

- *Osmotic effect*: Honey is a supersaturated sugar solution of fructose and glucose, which comprise 84 %. The interaction of the sugar molecules with water molecules leaves very little water available to support the growth of microorganisms.
- *Acidity*: Honey is acidic, with a pH ranging from 3.2 to 4.5 which is low enough to inhibit the growth of many pathogens.
- *Hydrogen peroxide* is the major antibacterial compound in honey. Bees secrete the enzyme glucose oxidase from nectar. It converts glucose in the presence of water and oxygen to glucuronic acid and hydrogen peroxide. Both the acid and hydrogen peroxide preserve and sterilize the honey during the ripening process.
- *Nonperoxide antibacterial factors*: There have been reports of isolation of various antibacterial chemical substances from honey
- Stimulation of the healing process, especially leg ulcers and diabetic ulcers.
- Speedy clearance of infection when used as dressing on infected wounds. Honey is reportedly extremely effective in the treatment of wounds infected with antibiotic resistant bacteria.
- Cleansing action on wounds: Honey has a debriding effect (removing dead, contaminated tissue) on wounds so that surgical debridement is unnecessary or only a minimum is required.
- Stimulation of tissue regeneration: Honey promotes the formation of clean healthy granulation tissue and growth of epithelia over the wound, thus helping skin regenerate. It has also been reported that dressing wounds with honey gives little or no scarring.

- Comfort honey dressings: Honey is nonirritating and the pain or discomfort associated with changing dressings is minimized.

The current main medical use of honey is in the treatment of infected wounds, chronic leg and skin ulcers, bedsores, especially in settings of drug-resistant infections (Cooper et al., 2002). The effectiveness of honey in wounds and ulcers has been known empirically for thousands of years and has recently been documented in clinical studies.

Honey is reportedly used by ophthalmologists for treating corneal ulcers in India and Russia where it has been used for chemical and thermal burns to the eye, conjunctivitis, and infections of the cornea.

Other traditional folklore medical indications of honey include peptic ulcers and gastroenteritis. At least two studies demonstrated that natural honey, but not commercial honey, was bactericidal against the bacterial isolates obtained and that different types of honey exhibited varying bactericidal concentrations (Haffejee & Moosa, 1985).

Much of the wisdom of folk medicine has its roots in ancient beliefs held by people who understood neither chemistry nor anatomy. Honey is just the latest of the ancient remedies to be “rediscovered.” There are abundant references in ancient writings indicating the beneficial effects of honey and other bee products.

The humble bee makes honey from countless varieties of plant blossoms, and it is logical to assume that by-products from the beehive such as honey contain many substances of medicinal value that modern medicine has yet to discover.

⁴Council of Forensic Medicine, İstanbul, Turkey

Medical science is one of the most important professions in our world. In the Ottoman Empire, which was made up of several climate zones with unique health problems, the medical system was enriched by numerous cultural and scientific influences. The Ottoman medical system was based on folkloristic medicine, religious medicine called “prophetic medicine,” and mechanistic humoral medicine inherited from Greek antiquity and the influence of Paracelsus (Shefer-Mossensohn, 2009).

Hospitals in the Ottoman Empire were divided into certain sections, and appropriate treatment protocols were given, if a diagnosis of the disease was possible. In particular, homeless and poor people were not neglected. They had the same stature as in today’s state hospitals; the people who were called *Gureba* enjoyed free cure centers.

Süleymaniye Medical School (Madrassa)

The Süleymaniye Complex, a formal teaching institution in the Ottoman Empire, was built in İstanbul by the Ottoman architect Sinan (1489–1588) for 8 years between 1550 and 1557 (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>). This complex sponsored by Kanuni Sultan Süleyman Han is surrounded by various parts of a medical school

called a Madrasa, a large hospital and other social buildings located in the Süleymaniye Mosque.

In the history of the Ottoman Empire, the Süleymaniye Medical Madrasa, which was built adjacent to other buildings in İstanbul, was the first medical school in Islamic civilization (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>). It had a special importance in Ottoman medicine in the education of physicians for both public and military needs. Moreover, the medical students at the Madrasa had free meals from the kitchen called *imaret*, and they practiced the theoretical knowledge they learned in school in the hospital called *dar al-shifa* (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>).

In the medical Madrasa, there was a staff including one lecturer called *müderris*, eight students called *danişmend*, and three auxiliary staff (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>). The students were taught from a total of 66 medical books at the Madrasa by the master-apprentice method (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>). The Süleymaniye Medical School was a very important place which provided physicians for all the medical institutions in the Ottoman Empire for about three centuries. Turkish medical lecturers at the Süleymaniye Medical School taught lessons on pathology and surgery for 4 days a week (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>). As far as we know, the Süleymaniye Medical Madrasa continued to educate the students until the middle of the nineteenth century. In addition to medical education, lessons regarding logic called *ilm-i mizan* and certain sciences called *fenn-i hikmet* or *ulum-i akliye* were taught at the school (<http://www.muslimheritage.com/article/suleymaniye-medical-madrassa>).

Mechanistic Humoral Medicine

Humoral theory describes the composition of matter and comments on illnesses. According to this theory, everything is composed of

four elements: air, water, fire, and earth (<http://www.muslimheritage.com/article/paracelsian-influence-ottoman-medicine>). Matter has four basic features: warm, cold, moist, and dry (<http://www.muslimheritage.com/article/paracelsian-influence-ottoman-medicine>). The body consists of four humors (fluids): blood (air), phlegm (water), yellow bile (fire), and black bile (earth). And there are four temperaments: sanguine, choleric, phlegmatic, and melancholic (Ullmann, 1978). Illness is a state of imbalance in the body, and the humoralist physician evaluates which of the four humors is in excess or deficiency (Shefer-Mossensohn, 2009).

Paracelsus' Concept of Medicine

After years of following Galen's concept of medicine, Paracelsus (1493–1541) changed medical practice, and this influenced modern Ottoman medicine (<http://www.muslimheritage.com/article/paracelsian-influence-ottoman-medicine>). According to Paracelsus, the elements had two different forms, external and internal. For example, the ego is an example of the internal element which provides for continuation of the species, while physic is related to the external element (Ullmann, 1978). In chemistry, the properties of the four elements are: earth, fire, water, and air (Kasîr al-Naf'. fol.: 4b; Omer b. Sinan: Ibid., No: 7,083, fols: 8a-b). Paracelsus suggested a relationship between the cosmos, the humanity, and the universe. Human beings and every illness should be studied together, as there is no disease and there are patients (Kasîr al-Naf'. fol.: 4a; Omer b. Sinan: Ibid., No: 7,083, fols.: 7b-8a).

The medicine of Paracelsus had a negative effect upon the Ottoman society because of the physicians' dependence on drugs righting the imbalance caused by disease (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Some Ottoman and European physicians used a new treatment protocol, called *tibb-i jadid*, composed of inorganic drugs which might have caused poisoning (Sarı, Zülfikar, & Yıldırım, 1993; <http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Head physician Gevrekâde Hafız Hasan Efendi (1724–1801) reported some complaints concerning various practices of European scholars in İstanbul (Sarı et al., 1993).

Ottoman Turkish Physicians

Ottoman Turkish physicians investigated the results of various clinical applications based on the traditional rules of humoral theory (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

Among the Ottoman physicians, Şerafettin Sabuncuoğlu (1385–1470), the author of a famous treatise on surgery called *Cerrahiyetü'l-Haniyye* (Imperial Surgery), the first illustrated surgical atlas, is a good example of these physicians (Fig. 1) (Turgut, 2007, 2008; <http://www.muslimheritage.com/article/15th-century-turkish-physician-serefeddin-sabuncuoglu-author-cerrahiyetu-%E2%80%98l-haniyye>). He went to İstanbul to present his book, the first example of an illustrated surgical textbook in both Turkish and İslamic medical literature, to the Fatih Sultan Mehmed Han in 1465. Today, there are only three copies of the book in the world (<http://www.muslimheritage.com/article/15th-century-turkish-physician-serefeddin-sabuncuoglu-author-cerrahiyetu-%E2%80%98l-haniyye>). The titles of Sabuncuoğlu's textbooks are *Cerrâhiyetü'l-Hâniyye* (Imperial Surgery), *Mücerrebname* (On Attempting), and *Terceme-i Akraadin* (Translation of Pharmacology).

Mastery in Ottoman Medicine

In the Ottoman Empire, two basic parameters of medical qualification for physicians were experience and mastery according to the trust of deeds, named *wakfiya* (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Fatih Sultan Mehmed Han was very

Hospitals and Medical Schools in the Ottoman Empire,

Fig. 1 Illustration of spinal traction technique for a patient with vertebra fracture-dislocation for a patient from Sabuncuoğlu (Reprinted with permission of the Atatürk Institute of Culture, Language and History, Institute of Turkish History from Uzel İ (1992))

H

interested in medicine (Uzel, 1992). Clinically, Ottoman Turkish physicians evaluated medical principles based on their personal experiences. They noted the special role of good clinical practice in their books. In his book, Emir Çelebi said that it was not acceptable to repeat previous knowledge; physicians should add their own personal experience to the current literature (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Abbas Vesim Efendi noted that the physician should visit patients in the hospital regularly, since he may encounter formerly unknown interesting diseases. It is very important to examine the patients for their experience, as the physician will observe different diseases (Ural, 1998; <http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

Ottoman Turkish medical practitioners did not use unknown drugs or techniques in the treatment of patients. In the fifteenth century, Ibn Sharif suggested that physicians should not prepare drugs from unknown herbs and should try only well-known ones in their patients and those

experienced by oneself (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Ibn Sīnā's *Canon* was used as a reference both in western and eastern countries for centuries; until the beginning of the eighteenth century, his works were used as textbooks in European universities. Afterwards, they were updated by various medical specialists with their new contributions (Kürkçüoğlu, 1962). Ottoman traveler Evliya Çelebi (1611–1682 AD) reported an account illustrating a surgical procedure for bullet extraction in the seventeenth century (Turgut, 2010a).

In Ottoman medical practice, the *müderri*s in the Süleymaniye Medical Madrasa transferred the medical knowledge of Hippocrates, Galen, and Ibn Sīnā from the ancient Greek, Roman, and Islamic period to his students (Sarı, 1977; <http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). The first principle for all physicians was, “Do not harm the patient” (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Furthermore, the physician

must not use his/her patients as experimental animals (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). In Ottoman medical practice, it was advised to pay importance to nature's healing power (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

Treatment

According to Islamic belief, there is a perfect solution for every disease for which nature provides herbal treatments, called folk medicine. In classical Ottoman medicine, the treatment consists of administering a proper drug to correct an imbalanced temperament. Physicians gave only tested drugs (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

Nevertheless, it was possible to do some modifications of the known treatments through experiences by empirical methods, and these were usually kept as a secret and transferred from master to apprentice or from father to son (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). The experiences were valuable information for physicians, although they were not based on scientific methods. The traditional medical philosophy and treatments were based on the knowledge that both health and disease were related to the equilibrium of the four basic elements (Sarı, 2000).

Special written or oral consent, called *hujjat*, was taken from patients or their parents, before medical or surgical treatment, in case there was an action against the physician because of injury or death (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). An agreement (contract) was prepared and signed by witnesses in the presence of the judge called *kadı* (Porter, 1835). As a rule, the judge of the canonical courts, appointed by the Palace, handled different legal problems

regarding relationships between physicians and his patients.

According to Ottoman rule, physicians were not considered responsible for the possible complications of various treatments, in the presence of a written consent, a medical failure, or a surgical technique consistent with well-known medical standards (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). To solve a dispute resolution, an expert surgeon/physician called *ehl-i hibre* was appointed by the judge, and if the practitioner was found to be responsible, he was to compensate for all harm done (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>).

Principles of patients' rights were observed by the Ottomans so that a regulation was published which underlines the behavior of the physicians to their patients. In this regulation, physicians were told to be tender and sincere and to be efficient in their fields. The physicians in Devlet-i Ali Osmaniye followed the examples of medical scientists such as al-Zahrāwī and İbn Sīnā.

Music Therapy for Patients with Mental Disease

Every patient had a special importance, and a proper treatment protocol was given according to the disease. For patients with mental disease, a psychiatry hospital was founded on the borders of the Ottoman Empire. A new era began when Sultan II. Bayezid Han, the son of Fatih Sultan Mehmed Han, constructed the Sultan Bayezid II Külliyesi (Fig. 2). Patients with mental disease were cured not only by medical treatment protocols but also by music therapy in this hospital. There were students studying medical science in the Madrasa inside the complex which is also adjacent to a mosque – called Külliye.

Another center for cure was Devlet-i Ali Osmaniye, Süleymaniye Medical Madrasa, which

Hospitals and Medical Schools in the Ottoman Empire, Fig. 2 Illustration of application of traction method for a patient with back problem in Sultan Bayezid

II Külliyesi which was built by Sultan II. Bayezid Han (r. 1481–1512) in 1488 (Reprinted with written permission of Mr. Veysel Engi from his personal photo archive)

H

Kanuni Sultan Süleyman Han ordered to be built by Mimar Sinan. In this Madrasa, the students were studying medical science while having the chance of practical studies in the hospital (Turgut, 2010b). In Darüşşifa, treatments were free and drugs were provided free twice a week to other patients. Other important health centers of the Ottomans were Bayezid Darüşşifa in Bursa and Fatih and Sultan Ahmet Madaris in İstanbul. The health centers were the cornerstones of improvement in medical science (Turgut, 2010b). The foundations developed in the classical period formed the basis of medical science for centuries.

Studies in Ottoman Medicine

Hydrotherapy and Hygiene

European travelers reported the high level of hygiene in the Ottoman world. Water was used not only for hygiene but also as a therapeutic tool. Ottomans bathed in public baths called *hamam*, which were well known and safe in the Muslim community, pools, and rivers (Shefer-Mossensohn, 2009). In the hospital, the hamam was a part of the institution, and bathhouse attendants called *dellak* or *külkhani* maintained the personal hygiene of the patients (Shefer-Mossensohn, 2009).

Effects of Europeans on the Ottomans

Members of the medical Madrasa in İstanbul were not able to communicate with their colleagues in the Europe, because they didn't know European languages (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). However, Ottoman physicians realized that many diseases were contagious. Therefore, diseased people were held in isolated places where healthy people could not go.

Mustafa Behçet Efendi (1774–1834) who was the founder of the Tibhane-i Amire is considered the pioneer of current medical schools in Turkey (<http://www.muslimheritage.com/article/evolution-attitudes-towards-human-experimentation-ottoman-turkish-medicine>). Also, it was considered vital to speak a European language to be a good physician (Efendi, 1259; Ülman, 1995). In the nineteenth century, European medicine had a major effect upon Ottoman medicine, but the classic Islamic works and Hippocratic medicine were also used. According to legal regulations, the Civilian School of Medicine (Mülki Tibbiye) and the Military Medical School, called Mekteb-i Tibbiye-i Şahane, educated students for medical practice in the Ottoman Empire (Sarı, 1977). Most of the physicians educated at the Ottoman medical school went to different European

Hospitals and Medical Schools in the Ottoman Empire,

medical institutions to gain clinical experience in their area.

As a unique sample of medical textbooks in the Ottomans, the *Cerrâhiyetü'l-Hâniyye*, which was dedicated to Fatih Sultan Mehmed Han, was written in Turkish. This book consists of three chapters divided into a total of 193 sections, including abundant colorful, descriptive drawings of surgical instruments and certain operations in the miniature format (Turgut, 2007, 2008; <http://www.muslimheritage.com/article/15th-century-turkish-physician-serefeddin-sabuncuoglu-author-cerrahiyetu-%E2%80%98l-haniyye>). In addition, Sabuncuoğlu added his own experiences based on his practice of surgery. Sabuncuoğlu drew his own color miniatures of surgical procedures (Figs. 3 and 4).

Şerafettin Sabuncuoğlu cites previous pioneers including Hippocrates, Ibn Sīnā, Galen, and al-Zahrāwī. In addition to different surgical instruments described by al-Zahrāwī, he illustrated new surgical interventions. The use of human images in the book marks a very important revolution in Turkish-Islamic medicine. The *Cerrâhiyetü'l-*

Hâniyye clearly demonstrates the high level of Turkish surgery in the Ottoman Empire during the fifteenth century (Turgut, 2007, 2008; Uzel, 1992).

Cerrâhiyetü'l-Hâniyye contains a total of four sections: cauterization techniques, general surgery including pediatric surgery and plastic surgery, orthopedics, and various medical preparations (Fig. 5) (Turgut, 2007, 2008; Uzel, 1992). In addition to many original contributions, Sabuncuoğlu's book is unique for the excellent illustrations that demonstrate the surgical interventions by showing the patients (Turgut, 2007, 2008). Sabuncuoğlu practiced not only as a surgeon but also as a general physician.

Surgical Procedures

In *Cerrâhiyetü'l-Haniyye*, there are a total of 191 sections on different surgical specialties, giving detailed information regarding the diagnosis, classification, and surgical techniques (Turgut, 2007). Şerafettin Sabuncuoğlu describes the management of some neurological diseases

Start of Radiology in Ottomans

The discovery of X-rays by W. C. Roentgen in 1895 was immediately applied all around the world (Ülman, Livadas, & Yıldırım, 2005). The X-ray was added to Ottoman medicine by Esad Feyzi (Ülman et al., 2005). The first radiographies in Turkey were taken at the Imperial Medical School in 1896 by Esad Feyzi, who was an intern doctor having installed the first roentgen machine in İstanbul (Ülman et al.). One year later, he took X-rays of soldiers wounded at the Turkish-Greek war which might be the earliest example of imaging bullets and shrapnels embedded into the body of the wounded soldiers (Bir Kesf-i Muhim, 1896). More importantly, this might have been the first application of the X-ray method into military surgery all over the world (Ülman et al., 2005).

Another significant contribution by Esad Feyzi was his book entitled *Roentgen Rays*,

their Medical and Surgical Applications, published in 1898, which is the first work ever written on X-rays in Turkey (Ülman et al., 2005). Among the various fields covered in this book were proper localization of bullets and shrapnels embedded into the body, identification of foreign bodies aspirated into the esophagus, diagnosis of bone, kidney, and bladder stone diseases, and forensic medicine (Fig. 7) (Feyzi, 1899; Ülman et al., 2005).

Esad Feyzi's article published in *Nevsal-i Afiyet* (Yearbook of Health) was the first scientific article on the clinical use of X-rays in Turkish medical literature (Ülman et al., 2005). He succeeded in incorporating radiological examination as a specific branch of the surgical clinic (Dr. Rifat, 1905). Apart from İstanbul, İzmir (Smyrna) was the first Anatolian city where X-rays were used at the beginning of the twentieth century (Solomonides, 1955).

Hospitals and Medical Schools in the Ottoman Empire, Fig. 7 The hand radiograph of Boyabatlı Mehmed, one of the 1897 Greco-Turkish War veterans, is being taken by Roentgen apparatus integrated by Esad Feyzi and Rifat Osman (Feyzi, 1899)

Forensic Medicine

In the Ottoman Empire, there were anatomists such as Şemseddin-İtaki providing major contributions to medicine in the seventeenth century (Fig. 8) (Kahya, 1996), but the emergence of forensic medicine was a result of a modernization project through the nineteenth century. The first medical school called Mekteb-i Tibbiye-i Şahane (Royal School of Medicine) was established by Sultan Mahmud II Han for the army's health in 1839 (Gök, 1995; Gök & Özen, 1982). The first autopsy was done in 1841 by Dr. Charles Ambroise Bernard at this school, and the first description of the autopsy was noted in the book *Makalatı-Tıbbiye* written by Hayrullah Efendi (1820–1869) in 1843 (Gök, 1995; Oğuz & Cem, 2009). Afterward, the Department of Medical Jurisprudence in Zabita Tababet-i Adliye was established in İstanbul (Şehsuvaroğlu & Özen, 1974). The first morgue office was established in Sıhhiye-i Umuriye (Gök & Özen, 1982; Şehsuvaroğlu & Özen, 1974).

Huangdi Jiuding Shendan Jing

Fabrizio Pregadio

The *Huangdi jiuding shendan jing* (Book of the Divine Elixirs of the Nine Tripods of the Yellow Emperor) also known as *Jiudan jing* (Book of the Nine Elixirs) is one of the earliest extant Chinese alchemical texts. Quotations and other references in Ge Hong's *Baopu zi neipian* suggest that the text circulated in a form at least substantially similar to the current one by the end of the third century. The extant version, dating from the latter half of the seventh century, is found in the *Daozang* (Daoist Canon). It is followed by an extended commentary that represents in its own right a compendium of early medieval Chinese alchemy.

Besides its early date, the *Book of the Nine Elixirs* is significant as it provides one of the most complete descriptions of the alchemical practice in China, from the preliminary rituals to the compounding and ingestion of the elixirs. The ritual features include purifications, interdictions, secrecy, retirement, choice of time, delimitation of space, and ceremonies for transmitting the text, for starting the fire, and for ingesting the elixirs.

The compounding begins after the preliminary ritual practices. The first step consists in the preparation of an amalgam of refined lead and mercury, said to contain the essences of Heaven and

Earth, or Yin and *Yang*. This compound is used as a layer in the crucible together with the ingredients of the elixirs. Then one prepares a mud used for sealing the crucible and prevent the loss of *qi* (energy), thus recreating inside the vessel conditions similar to those of primeval chaos.

The methods of the Nine Elixirs proper are based on processes of sublimation (*fei*). The substances most commonly used are mercury, orpiment, realgar, malachite, arsenolite, magnetite, cinnabar, alum, and hematite. The ingredients are first placed in a tightly sealed crucible, and heated on a fire progressively made more intense. After the required number of days, the crucible is left to cool and is opened. The essence is carefully collected from the higher part of the crucible, and mixed with a moistening substance. The elixirs should be ingested at dawn, facing the sun. Their ingestion is said to bestow eternal life, command over gods and spirits, protection from calamities, and sometimes magical powers. Some of the Nine Elixirs can be transmuted into alchemical gold. The text emphasizes that the purpose of this final transmutation is to make sure that the compounds have been correctly prepared.

Huangdi Neijing

Richard Bertschinger

The *Huangdi Neijing* (Yellow Emperor's Inner Canon) is the most famous and oldest medical classic of China, being compiled by various unknown authors from the period of the Warring States (475–221 B.C.E.) onward. The book consists of 2 main sections, each of 81 chapters: the *Suwen* (Plain Questions) and *Ling Shu* (Miraculous Pivot), the latter being earlier entitled the *Zhen Jing* (Needling Classic).

These texts are the very earliest to be written on Chinese medical theory. However, Keegan has shown conclusively that none of the *Neijings* now extant are the original. Lu and Needham also summarized the evidence and considered that the corpus was probably already well formed by the first century B.C.E.

The Canon achieved something close to its known form with the recension (ca. A.D. 762) which came about with the editorship of Wang Ping during the Tang dynasty. Another edition, the *Huangdi Neijing Taisu* (Great Simplicity), recently discovered in Japan, may be considered closer to the original text. The insertion of chapters into the text, including those on *wuyun liuqi* (The Theory of the Five Elemental Cycles and Six Climates), undoubtedly took place some time close to the mid-tenth century (Lu & Needham, 1980). Since this date, however, the contents have been fixed.

The book takes on a question and answer form, in which the legendary Yellow Emperor questions his ministers about the need for a medical reformation, in accord with the prevailing tone of Han thought. In the opening paragraphs the Emperor questions his minister-physician Qi Bo:

The Yellow Emperor asked: "I have heard that the men of ancient times lived through a hundred springs and autumns, and remained active and did not reach senility. Now our men only reach half

that age and they are senile. Are we so very different? Or have we missed something?"

Qi Bo replied: "The men of ancient times, they understood the Way, they modelled themselves on Yin and Yang and were at peace with the arts of guiding their destiny. They ate and drank in moderation, they rose and retired at regular hours, neither made wild schemes, nor wearied their bodies at work. . . . The men of the present day are not the same. They drink liquor to excess, they take wild thinking as the norm. When drunk they perform the act of love, seeking to exhaust their energies and waste their lives. They do not know how to be content. They have no time to control the passage of their thoughts, looking only for what cheers – not for the joys of health" (Ch. 1).

This sets the tone for the preventative and rehabilitative character which dominates Chinese medicine. Later in the chapter, the same need for ataraxia (peace of mind) is stressed:

Detach and be at peace, humble and empty – and the true energies will follow. The vital spirit, guard it within! How then can disease arrive?

Among the Canon's other ideas are the well-developed tract system of 12 main channels and numerous collaterals (the *jingluo*); and the science of the 5 elements (*wuxing*): fire, earth, metal, water, and wood. It also introduces the classificatory dialectical tool of *Yin/Yang* (earth/heaven, dark/light, night/day, solid/hollow, etc.). Many chapters also describe the relationship between human beings and their environment, and refer in great detail to circadian, or internal, rhythms within the body. These biological clocks foreshadowed the modern science of chronobiology.

Surgery is also mentioned, and the *bian* stone needle as the forerunner of acupuncture. The Canon accurately identifies gangrene in the feet and says it is more common in the toes, where it advises amputation to save lives. This is just one of the many ideas prevalent in the book which accords with modern medical theory.

Huangfu Mi

Hong Wuli

Huangfu Mi was born in 215 in Anding Chao'na (now Pingliang County, Gansu Province) and died in 282. He was born to a poor family and did not receive any education until he was 20 years of age, after which he devoted all his time to reading, extensively and intensively, all kinds of ancient literature. He eventually became a great master in the art of classics.

During the period 256–260, he suffered *Feng Bi* or apoplexy and became hemiplegic. From then on, he began to study medicine. In view of the overlapping of many texts in several medical classics, he decided to compile a new book on the art of acupuncture and ► [moxibustion](#) under the principle of "sorting out the similarities, excluding the meaningless and useless words and sentences, deleting unnecessary repetition and extracting the essence". He did this by incorporating the relevant portions from the three classics, namely ► [Huangdi Neijing su wen](#) (*Plain Question of Huangdi's Inner Canon*), *Zhenjing* (*Classic of Acupuncture*), and *Ming tang kong xue zhen jiu zhi yao* (*Essentials of Treatment for Acupuncture and Moxibustion with Anatomical Charts and Acupoints*).

A 12-volume *Zhen jiu jia yi jing* (A-B classic of Acupuncture and Moxibustion) was written and divided into two parts. One of them deals with the physiology of the human body, indications for each acupoint, diagnostic measures, way of puncturing, and pathophysiology. The other part is devoted to clinical knowledge, including internal medicine, surgery, pediatrics, and gynecology, with special reference to internal medical science. Emphasis is laid on the unification of channels and acupoints and on exploration of indications and contraindications for acumoxibustion therapy. This work, from which most of the works on acupuncture and moxibustion of later ages were derived, exerted great influence on the development of the art of acupuncture and moxibustion in successive generations. Erudite and learned, Huangfu Mi was very productive in his writings, including works on history and classical literature.

During his time, it was a custom to swallow processed stone remedies for seeking longevity and as an aphrodisiac. Huangfu Mi also practiced this behavior and was brought to the brink of death after a critical illness. After he fortunately recovered, he wrote a book, *Han shi san lun* (On Stone Powder To Be Swallowed Cold) to advise people to avoid such harmful and potentially fatal behavior.

Ḥunayn Ibn Ishāq

Albert Z. Iskandar

Abū Zayd Ḥunayn Ibn Ishāq al-'Ibādī (Johannitius A.D. 808–873), a physician, philosopher, and translator, was born in al-Ḥīrah (Hira), now southeast of al-Najaf (Iraq). He and his ancestors were Syrians who belonged to the Nestorian church. The family nickname, al-'Ibādī, is derived from “al-'Ibād,” a Christian Arab tribe.

Ḥunayn studied medicine in his youth in Baghdad. The thirteenth-century medical historian, Ibn Abī Uṣaybi'a, author of the book *ʿUyūn al-Anbāʾ fī Ṭabaqāt al-Aṭibbā* (Sources of Information about the Classes of Physicians), gives a lively account of the difficulties that confronted Hunayn as a student of medicine. Yūḥannā ► [Ibn Māsawayh](#) (Mesue d. A.D. 857) was a famous physician and a highly respected teacher of medicine. He conducted classes in a vast room in his large house. Questions from young Hunayn, who was very keen on amassing knowledge, interrupted the serenity of Mesue's lessons. Mesue reprimanded Hunayn several times without effect, then finally ordered him out of the classroom and told him to give up medicine. Mesue advised him to trade in coins instead, which he believed would be financially more rewarding than the practice of medicine. Mesue had in mind the fact that most of the residents of Hira were merchants and money changers. So far as one can tell, Hunayn abandoned Mesue's tutorship and decided on self-education.

Bakhtīshūʿ Ibn Jibrāʾīl, a contemporary of Ḥunayn, held regular meetings at which physicians and philosophers debated questions and problems raised by Caliph al-Mutawakkil (d. A.D. 861). Ḥunayn was invited to attend these meetings at which he showed medical acumen. Al-Mutawakkil is reported to have endowed a school of translation, and appointed Hunayn as its head. Among the members of this school were Ḥunayn's son, Ishāq Ibn Ḥunayn (d. A.D. 910), who translated from Greek into Syriac and

Arabic. He also took charge of revising, against the original Greek, translations by his colleagues. It is worth noting that Ishāq's translations were carefully revised and corrected, whenever necessary, by Ḥunayn himself. Towards the end of his life, Ḥunayn embarked on an Arabic translation of Galen's *De partibus artis medicativae* (*On the Parts of Medicine; Fī Ajzā' al-ṭibb*), of which he had earlier rendered the Greek text into Syriac. Death prevented him from completing his translation. Ishāq attended to Ḥunayn's unfinished work.

Another eminent translator in Ḥunayn's school was his nephew, Ḥubaysh Ibn al-Ḥasan al-A'sam, who was involved in translating Galen's (d. ca. A.D. 200) *De anatomicis administrationibus* (*On Anatomical Procedures; Fī 'Amal al-Tashrīḥ*) into Arabic. This work consists of 15 books. It was translated into Syriac by Ayyūb al-Ruhāwī (Job of Edessa) for Jibrā'īl Ibn Bakhtīshū' (d. A.D. 828–829). A revised Syriac translation was made by Ḥunayn himself for Yūḥannā Ibn Māsawayh. It is generally accepted that Ḥubaysh produced an Arabic version about the end of Ḥunayn's life, and with his active collaboration.

Ḥunayn's school of translation helped to establish a firm foundation upon which medieval Arabic medicine and allied sciences were securely built. Renowned Arabic-speaking physician-philosophers, like ► [al-Rāzī](#) (Rhazes d. A.D. 925) and Ibn Sīnā (Avicenna d. A.D. 1037), and many others, owe Ḥunayn and members of his school a great debt for rendering fundamental Greek texts of antiquity into Arabic, the language of learned men at the time.

Al-Mutawakkil elevated Ḥunayn to the post of Chief Court Physician and dismissed Bakhtīshū' Ibn Jibrā'īl. The latter conspired against Ḥunayn, and, unfortunately, Ḥunayn fell from grace. Al-Mutawakkil ordered the sequestration of Ḥunayn's entire library.

Ḥunayn was 48 when he compiled the first draft of his *Risālat Ḥunayn Ibn Ishāq ilā 'Alī Ibn Yaḥyā fī Dhikr mā Turjima min Kutub Jālīnūs bi-'Ilmih wa-ba'd mā lam Yu-tarjam* (Missive to 'Alī Ibn Yaḥyā on Galen's Books Which, so far as Ḥunayn Knows, Have Been

Translated, and Some of Those Books Which Have Not Been Translated). The fact that Ḥunayn's *Missive*, which presents impressive information about some of his predecessors and contemporaries, was compiled, he says, after the loss of his library, indicates his complete dedication to his work. 'Alī Ibn Yaḥyā, to whom Ḥunayn's *Missive* was dedicated, was a powerful friend and a private confidant of Caliph al-Mutawakkil. Through his intercession, Ḥunayn later recovered his own library.

The following are a few examples to shed light on the depth of Ḥunayn's involvement in translating Galen:

- The *Pinax* (*Index; Fīnaks*) was translated into Syriac for a doctor named Dā'ūd and into Arabic for Muḥammad Ibn Mūsā
- *De ordine librorum suorum* (*On the Order of His Books; Fī Marātib Qirā' at Kutubih*), into Arabic for Aḥmad Ibn Mūsā
- *De sectis ad eos, qui introducuntur* (*On Sects; Fī' al-Firaq*, into Syriac when Ḥunayn was 20 years of age, and another translation for Ḥubaysh when Ḥunayn was 40
- *De febrium differentiis* (*On the Types of Fevers; Fī Aṣnāf al-Ḥummayāt*), the first book to be translated by Ḥunayn, into Syriac, and another translation for his son when he discovered textual gaps which he filled in by collating against other manuscripts, and again into Arabic for Abu'l-Ḥasan Aḥmad Ibn Mūsā
- *De crīsis* (*On Crisis; Fī' al-Buḥrān*). First Ḥunayn corrected a Syriac translation by Sergius of Resaina (d. A.D. 536), then produced an Arabic version for Muḥammad Ibn Mūsā. All these and many more are discussed in detail in Ḥunayn's *Missive*

In spite of his fame as a translator, he was scoffed at by doctors when he wished to practice the art of physic. They admitted that he was an excellent translator, yet he was not a doctor, in the same way that a blacksmith could forge a beautiful sword without himself being a swordsman.

Ḥunayn was also a medical author in his own right. His books are mainly based on Greek sources, such as: *Fī Awjā' al-Ma'idah*

(*On Stomach Ailments*) and *al-Masā'il fi'l-tibb li'l-Muta'allimīn* (*Questions on Medicine for Students*). His book entitled *al-ʿAshar Maqālāt fi'l-ʿAyn* (*The Ten Treatises on the Eye*), covering both the theory and practice of medicine, ranks highly among medieval books of ophthalmology.

Historians of medicine and science are greatly indebted to Hunayn and his school of translation. Without their efforts, many of the works of antiquity would have probably been lost forever. Two examples will suffice. Galen's *On Anatomical Procedures* (*Fī ʿAmāl al-Tashrīḥ*) of which Books IX (in part) and X–XV (inclusive) are lost in the original Greek, is preserved in its entirety in Arabic manuscripts. Again, Galen's book *De optimo medico cognoscendo* (*On Examinations by Which the Best Physicians are Recognized*) is entirely lost in the original Greek. Hunayn's Arabic version has survived in two manuscripts.

Huntian

Christopher Cullen

Needham Research Institute, Cambridge, UK

Huntian is the Chinese name for a scheme of cosmography, often mentioned as in opposition to the ► [gaitian](#). According to explanations of this scheme, heaven is a sphere surrounding a flat earth whose upper surface lies across its diame-tral plane. Heaven is therefore continuous (*hun hun ran*), unlike the situation described by the *gaitian*, under which heaven has a boundary. The heavenly sphere rotates once daily about an axis inclined at 35° to the horizontal, carrying with it the heavenly bodies, whose risings and settings occur as they move above and below the plane of the earth's surface. The Chinese observer is imagined to be at the center of the earth, and hence at the center of the heavenly sphere. Since the latitude of most ancient Chinese capi-tals was about 35° north, the *huntian* universe

acts as a sort of cosmic planetarium for the official astronomers at those capitals. Observers near the edge of the earth would see a very odd and asymmetrical series of celestial phenomena, but the diameter of the sphere is so large (one version gives a figure equivalent to over 140,000 mile) that the entire inhabited world is effectively at the center of the universe.

The first full account of the *huntian* cosmography is that of ► [Zhang Heng](#), written ca. AD 117. Thereafter it is the usual scheme referred to by those concerned with mathematical astronomy, and a number of texts point out its advantages compared with the *gaitian*. The innovation of the *huntian* was apparently connected with the introduction of the armillary sphere in China at some time after 100 BCE. The nested rings of such an instrument are highly suggestive of the skeleton of the celestial sphere. It would be a mistake, however, to see debates on cosmography as a crucial concern for astronomers in China, since the algebraic/arithmetic character of Chinese mathematical astronomy meant that the detailed geometry of the cosmos was much less of an issue than it was in ancient Greece and Renaissance Europe.

Hunting in Amazonia

Glenn H. Shepard Jr.
Department of Anthropology, Museu Paraense
Emílio Goeldi, Belém do Pará, PA, Brazil

Hunting is an important food source for Amazon forest dwellers, indigenous and nonindigenous alike. Hunting and predation also represent central concepts in the worldview and social organization of native Amazonian peoples. Both

Hunting in Amazonia, Fig. 1 A Matsigenka bow hunter on the upper Manu River, Peru, 1996

approaches – hunting as a subsistence activity or ecological adaptation and hunting as a social and symbolic practice – are essential for understanding the impact of local livelihoods on Amazonian biodiversity. Unfortunately, the divergent methods and theoretical orientations of these potentially complimentary approaches rarely if ever create a dialog in the scientific literature.

Hunting became a central concern in the 1970s for anthropologists attempting to understand the supposedly low levels of sociocultural complexity of Amazonian indigenous peoples (Fig. 1). Archeologist Betty Meggers (1971) suggested that Amazonia was a “false paradise,” imposing ecological limitations on the growth and social stratification of native societies from ancient times through the present. A whole field of ecologically oriented anthropological studies grew up around the “protein debate,” namely, whether protein capture was a limiting factor on historical and modern Amazonian societies (Gross, 1975).

The debate turned out to be largely spurious, since, as Beckerman (1979) said, protein from aquatic animals, terrestrial game, and even vegetable sources turned out to be more abundant than originally estimated. Moreover, recent archeology has demonstrated far more densely settled and complex societies in prehistoric times than those observed in the ethnographic record (Denevan 1976; Heckenberger et al., 2008). Though the protein debate faded away, quantitative studies on hunting and other subsistence activities by Amazonian communities continued, becoming heavily influenced by microeconomic theory (Alvard & Kaplan 1991; Hames & Vickers, 1982; Hawkes, Hill, & O'Connell, 1982). "Optimal foraging" models predict that hunters' choices will be largely constrained by practical considerations maximizing protein return for time invested, which is to say, "bringing home the biggest bacon" (Jerozolinski & Peres, 2003).

But hunting for indigenous societies of the Amazon is not just a means of obtaining protein. The exchange of meat is important in defining social, political, and even sexual relationships (Siskind 1973). In the Amazonian cosmos-as-ecosystem, hunting is a fundamental metaphor that structures the mutual exchanges, ecological as well as cosmological, between humans, animals, and the spirit world (Reichel-Dolmatoff, 1976; Århem, 1996). Just as humans hunt and kill animals for food, so do certain dangerous animals, demons, and other spirits look upon humans as animals of prey. Widely shared across native Amazonian societies are myths about how primordial humans were transformed into animals and other beings. Despite this transformation in their outward appearance, all such beings retain their fundamental human nature and, indeed, continue to view themselves as humans.

According to the mythology of the Matsigenka people of Peru, for example, the snake is a hunter with poisonous arrows (Shepard, 2002a). The hunter himself is invisible: the snakes that human beings see are his arrows. The snake views himself as a human being, out in the forest, hunting for his family. When he looks at a human person, he sees a tapir, a peccary, or

some other animal of prey, which he shoots and kills to feed his family. Likewise the Matsigenka believe that the spirits of hunted animals can take revenge on a human hunter's family, making small children fall ill or die suddenly, thus reversing the role of predator and prey in a cosmological tit-for-tat (Shepard, 2002b). In the fluid Amazonian worldview, rife with transformations across species boundaries, most beings are both human and animal; their status in any given relationship depends on the point of view, or what is called "cosmological perspective" (Viveiros de Castro, 1996). This prolific area of anthropological study, intellectual heir to the structuralist paradigm of Claude Lévi-Strauss, is thus called "perspectivism." Indigenous rituals and practices associated with hunting are often concerned with re-signifying the killing of the animal to remove its human subjectivity so that the predatory act will not be interpreted as an act of warfare by the offended animal spirit (Fausto, 2007) (Fig. 2).

Both cosmological concepts and practical considerations influence the dietary choices of Amazonian populations, native and otherwise, through restrictions and taboos on their consumption of game animals, fish, and other foods. Indigenous as well as nonindigenous riverine Amazonian peoples may avoid or reject meats and fish with particularly strong or unusual odors, especially during periods of ritual vulnerability like pregnancy, *couvade*,¹ illness, or old age (Murrieta, 2001; Piperata, 2008; Shepard, 2004). Ross (1978) interprets game animal taboos in Amazonia as adaptive responses, aimed at protecting particularly vulnerable species. However Milton's (1991) comparative study documents such a wide variety of dietary taboos among different indigenous societies that any single ecological explanation would be too simplistic; instead, symbolic considerations and notions of group identity appear to be the overriding factor. Yet biologists and ecological

¹The custom in some cultures in which a man takes to his bed and goes through certain rituals when his child is being born, as though he were physically affected by the birth

Hunting in Amazonia, Fig. 2 If possible, Matsigenka hunters avoid touching the animals they have killed, leaving close kinsmen such as a brother-in-law to carry the animal home. In this way, the hunter avoids contaminating himself with the animal's blood and strong odor, which could offend the animal's spirit. The practice also ensures that meat is shared among kin (Manu, Peru, 1996)

anthropologists tend to overlook or ignore altogether the role of food taboos and other cultural factors influencing hunters' choices (see Shepard, 2002b) (Fig. 3).

The spatial impacts of hunting pressure are also influenced by variable social systems and cultural norms. Yanomami villages, for example, periodically migrate, creating a "reticular" rather than "central-place" pattern of resource use (Albert & LeTourneau, 2007). Indigenous hunters of the Guyana region appear to avoid sacred places in their hunting excursions, though ecological and geographic factors also strongly affect their choices (Read, Fragoso, & Silvius, 2010). Variable local beliefs and practices related to hunting and food consumption ultimately

Hunting in Amazonia, Fig. 3 White-lipped peccaries are among Amazonian hunters' favorite prey (Manu, Peru, 2007)

influence hunters' behavior and modulate their impact on the local fauna. Developing adequate community-based management systems necessarily requires understanding and leveraging such local concepts (Shepard, 2002b; Vieira, von Muhlen & Shepard, *in press*).

With growing international concern over the erosion of Amazonian biodiversity, ecological anthropologists and tropical biologists have invested much research effort in evaluating the impact of hunting by indigenous and other local populations on vulnerable animal species (Alvard, Robinson, Redford, & Kaplan, 1997; Ohl-Schacherer et al., 2007; Peres, 2000; Robinson & Bodmer, 1999; Sirén, Hamback, & Machoa, 2004; Souza-Mazurek et al., 2000). "Sustainability indices" have been used to calculate the maximum sustainable harvest for different animal species (Robinson & Redford, 1991). Yet such indices depend on detailed quantitative inputs about hunting activity in the study communities, requiring extensive fieldwork. Ongoing empirical research is essential, but it is impractical to conduct hunting surveys in every community to develop case-by-case management strategies. As a way of streamlining conservation planning, computerized modeling techniques have been developed to simulate the intensity and extent of depletion of key species through space and time across different management strategies (Levi, Shepard, Ohl-Schacherer, Peres, & Yu, 2009; Shepard, Levi, Neves, Peres, & Yu, 2012) (Fig. 4).

Hunting in Amazonia, Fig. 4 Spatial modeling described in Levi et al. (2009) and Shepard et al. (2012) allows communities and conservation planners to better

understand the long-term impacts of different management scenarios on the depletion of key game animal species

H

Some conservation biologists question the traditional view of indigenous societies as innate defenders of nature, especially once they adopt Western technology (Redford, 1991). Many conservationists fear that growing, Westernizing indigenous and other local populations will decimate biodiversity (Robinson, 1993; Terborgh, 1999; Peres, 2011). Defenders of indigenous people, however, have contested that indigenous reserves are as efficient as parks at preventing deforestation and fires (Nepstad et al., 2006) and that the “biodiversity cost” exacted by indigenous groups is compensated if they are empowered to deter incursions by more destructive loggers, miners, and ranchers (Yu, Levi, & Shepard, 2010; Zimmerman, Peres, Malcolm, & Turner, 2001). Moreover, indigenous reserves and other human-inhabited protected areas account for more than half of all forest reserves in Amazonia (Peres, 1993), meaning that the conservation of vertebrate biodiversity on a large scale must contemplate the management of hunting by local populations, ideally with their participation (Chapin, 2004; Sheil & Lawrence, 2004) (Fig. 5).

If biodiversity is to be conserved across Amazonia, hunting management strategies must be biologically sound, socially and culturally

Hunting in Amazonia, Fig. 5 As indigenous hunters adopt firearms, their impact on game animal populations increases dramatically (Rondonia, Brazil, 2001)

sensitive, as well as practical and enforceable on the ground (Yu et al., 2010). Hunting is a complex and variable socio-environmental practice, and adequate management requires ongoing dialog across multiple disciplines and collaboration between local people, scientists, and conservation planners.

Hydraulic Engineering at Angkor

Damian Evans

Departments of Archaeology and Asian Studies,
University of Sydney, Australia

The network of water management infrastructure that was developed in the heartland of the Khmer Empire during the classical Angkor Period (approximately ninth to fifteenth centuries AD) is one of the signal engineering achievements of the preindustrial world. Over several centuries, an elaborate and sophisticated water management system was developed over an area of approximately 1,500 km² around the great monuments of Angkor (Fig. 1). The network integrated and sustained a thriving metropolis of several hundred thousand people, located at the heart of an Empire that dominated mainland Southeast Asia for half a millennium. At the same time, it may have created a range of challenges to the long-term viability of that urban complex and to the Angkorian civilization itself (Evans et al. 2007).

The broader network consists of three major components: an upstream system of diversions, canals, and dams designed to alter the natural flow of water across the Angkor plain and channel water toward the central monumental zone; a central system of temple moats and vast reservoirs (known locally as *baray*) designed to store that water (Fig. 2); and a downstream system of canals radiating out from the center designed for the dispersal of stored water (Kummu 2009). With the exception of a handful of masonry spillways and culverts, and perhaps some wooden elements that have long since rotted away, the system is made almost entirely of earth: the channels and reservoirs were dug by hand, with the spoil from those excavations used to form earthen banks. Remnant traces of the system can still clearly be identified from the air (Fig. 3), and studies of archaeological topography have been used to reconstruct the overall structure of the system. However, the system is so complex, and so spatially and temporally extensive, that it is difficult at

Hydraulic Engineering at Angkor, Fig. 1 Archaeological map of Greater Angkor (Christophe Pottier and Damian Evans; background data NASA & JICA)

this stage to arrive at detailed or sophisticated models of its chronological development. However, we can see the broad outlines of major new developments from the beginning of the ninth century (in Phnom Kulen) through to at least the twelfth century (Fletcher et al. 2008).

The greater Angkor area was perhaps the most extensive urban complex of the preindustrial world, and the water management network played a crucial role in functionally integrating the vast inhabited landscape and providing a mechanism of transportation and communication. The stones that were used to build the monuments, for example, were floated down from distant quarries to temples like Angkor Wat by way of canals. In addition to these functional aspects, the waters of Angkor had powerful ritual and symbolic dimensions. They represented the cosmic oceans of Hindu-Buddhist mythology, rendered quite literally into the sacred geography of the earthly realm. Royal programs of

infrastructural renewal and hydraulic engineering reflected a ruler's mastery over the elements and were a key foundation of Angkorian kingship. It is important to note, however, that not all of the system was state-sponsored or controlled and that manipulation of land and water occurred at all scales, right down to the level of individual farmers digging household ponds and building small earthen dams to retain floodwaters.

The question of whether the large-scale system was used for irrigation has been controversial (Pottier 2000). One of the key challenges to the viability of inland agrarian civilizations in monsoon Asia is the sharp seasonality of the rainfall, which can produce an overabundance of water during the wet season followed by severely arid conditions during the remaining half of the year. Furthermore, subsistence-level rice farmers, who depend on the monsoon rains to flood (Fig. 4) their fields and produce a single crop per year, are very vulnerable to annual fluctuations in rainfall.

H

Hydraulic Engineering at Angkor, Fig. 2 Angkor Wat and moat, with the West Baray and medieval canals in the background

Hydraulic Engineering at Angkor, Fig. 3 The temple of Banteay Samre with remnant traces of ponds and canals in the immediate area

Hydraulic Engineering at Angkor, Fig. 4 The patchwork of walled rice fields on the Angkor plain, with the Phnom Kulen ranges in the distance

Since at least the 1940s, archaeologists have proposed that Angkor's engineered landscape was developed, at least in part, as a technical solution to those problems. In this view, by mitigating the risk of water scarcity at the seasonal and annual scale, the hydraulic network afforded a measure of food security – and potentially agricultural surpluses – that contributed substantially to the rise of Angkor. A related argument is that the network was unsustainable and created systemic vulnerabilities to longer-term social and environmental changes and that the failure of the system contributed to Angkor's decline. This “hydraulic city” hypothesis has attracted sustained criticism since the 1970s, and although new findings have in fact lent considerable support to the hypothesis, uncertainty still surrounds various aspects of the theory. For example, although recent studies have shown that Angkor's hydraulic network was technically capable of irrigating rice fields, providing a measure of food and water security, and producing significantly improved agricultural

yields, it still remains unclear to what extent this potential was actually realized.

Exactly when the water management system ceased to function also remains unclear and is the subject of ongoing investigations. For some parts of the system, such as the *baray* and several of the canals, there is evidence for episodic breakdown and rehabilitation throughout the Angkor period, perhaps indicating that the system was problematic from the very beginning and that significant resources had to be devoted to maintenance and repair (Lustig et al. 2008). In any case, it seems clear that the bulk of the system had fallen into disuse by the fourteenth or fifteenth centuries, although European accounts indicate that at least some canals in the central urban area were still functioning into the fifteenth and sixteenth centuries. With the dawn of the colonial period in the nineteenth century, almost all of the system was nonfunctional, although various elements (including two of the four great *baray*) have

been rehabilitated in modern times. Thus, even today, the medieval system still functions in a modified form.

Hydraulic Engineering in Ancient Peru and Bolivia

Charles R. Ortloff
CFD Consultants International, Los Gatos,
CA, USA
Research Associate, Department of
Anthropology, University of Chicago, Chicago,
IL, USA

As climate and weather variations played a major role in determining the agricultural strategies of societies in ancient Peru and Bolivia at their major sites (Fig. 1) (Binford, Kolata, & Brenner, 1997; Ortloff & Kolata, 1993), it is of interest to track the adaptive strategies those societies used

to combat uncertainties in agricultural production. Of most interest are those used to counter excessive rainfall and drought and their effect on agricultural field systems over different time periods. Such strategies arise from application of water engineering technology to defend/enhance agricultural production in the face of climactic stress. The defense strategies are specific to different geographic sectors, societies, and cultural periods and represent integrated programs to protect large investments in agricultural fields and water supply systems. Figure 2 shows many types of agricultural systems employed by different societies in different areas of pre-Columbian South America. Figure 2 organizes agricultural systems into categories supplied by surface water sources (rainfall, springs) and subsurface systems (groundwater) on the vertical axis and on the horizontal axis, for artificially created and natural farming surfaces. For each of these major categories, defense strategies to protect from excessive rainfall, floods, and drought exist along with performance and efficiency improvement strategies to increase agricultural yields under predictable weather patterns. Examples of all these strategies put into practice by ancient water engineers are found in the archaeological record and indicate that irrigation farming was truly a science practiced with considerable foresight and oversight to maintain productivity despite the many variations in climate and weather that influenced agricultural output.

While modern systems can use produce from different worldwide climate zones throughout the year, ancient systems had extreme vulnerability to climate- and weather-induced collapse of their systems. On this basis, the defensive measures listed in Table 1 give indication to the concern of ancient societies to protect their agricultural systems to the degree that their technology and innovative resources permitted. The catalog of defensive measures listed in Table 1 gives direct evidence of memory and response of past catastrophic climate and weather events and constitutes further evidence of the importance of such events in shaping the technological responses to protect agricultural fields systems and vital canal

Hydraulic Engineering in Ancient Peru and Bolivia, Fig. 1 Major site locations mentioned in the text

and aqueduct systems against excessive rainfall and drought episodes.

In Table 1, the + Rainfall notation denotes defense strategies exercised in excessive rainfall periods to protect vital agricultural systems; this category also includes efficiency improvements in water supply technology which have been observed in the archaeological record. The – Drought notation represents drought defense strategies and innovations observed in the archaeological record. Table 1 is divided into different spatial divisions of the Peruvian and Bolivian landscape (Fig. 1). These spatial divisions represent the Peruvian north highland sierra (as far north as Wari society occupation areas around Arequipa in Peru), altiplano regions characteristic of Lake Titicaca in highland Bolivia, and the Peruvian north and south coast valleys in different time periods from early

Preceramic/Formative times (2500–1600 BCE) to Late Horizon (LH) times (1400–1532 CE). The numbers in Table 1 refer to the application examples given as numbered listings 2–23 to follow.

Canal Flow Rate Controls and Use of Intravalley and Intervalley Canals for Drought Remediation

Examples of these include adjustable inlet blockages in the form of inserted reed mats and stone barriers at river canal intakes (*tomos*) to regulate flow rates into irrigation canals. Water supply canals frequently contained elevated overflow weirs activated by high water levels in canals when El Niño runoff into canals yielded flow rates in excess of their design capacity. The

Hydraulic Engineering in Ancient Peru and Bolivia, Fig. 2 Agricultural strategies used in the ancient Peru and Bolivia

weirs extracted excessive washed-in runoff water from the canal and conducted it to a lower-level reservoir or drainage ditch to alleviate erosion and overspillage damage to the main canal. In other cases, excessive rainfall runoff into a canal activated chokes (canal width contractions) that limited the flow rate at the contraction location – additional runoff flow elevated the upstream water height causing a side overflow weir to activate to release excess flow from the canal thus reducing erosion damage to the canal from excessive flow rates. Examples of sidewall

overflow weirs are present in the Chicama-Moche Intervalley and in the Jequetepeque Valley and the Farfan-Pacatnamu Canal systems (Ortloff, 2009; sections 1.2 and 1.3). Megacanal systems (e.g., the Chicama-Moche Intervalley Canal, Fig. 3) represent a tenth-century CE drought (Thompson, Mosley-Thompson, & Davis, 1995) remediation measure to redirect water from a valley with a large river (the Chicama River) to an adjacent valley of political importance (the Moche Valley with the Chimu capital city of Chan Chan) to restimulate

a defunct northern Moche Valley main canal (the Vinchansao canal, Fig. 3) formerly supplying water to field systems (Ortloff, 1993, 2009; Ortloff, Feldman, & Moseley, 1985; Ortloff, Moseley, & Feldman, 1983;) operational prior to the tenth-century CE drought. Elsewhere, the Lambeyeque-Supe-Leche Intervalley Canal system and the Lima Intervalley Canal complex (Kosok, 1965) provided canalized water diversion from valley rivers and extension of existing segments of intravalley canals to provide irrigation water to additional arable land areas not previously in production. A further subsidiary function of intravalley canals was to redirect water to fields close to valley necks to recharge the lower valley groundwater aquifer; the resulting higher water table limited irrigation canal seepage and evaporation from longer canals serving downvalley field systems and elevated groundwater for city wells. For normal operation of irrigation systems in predictable weather/climate patterns, additional field areas adjacent to and located in between the source and destination

valleys of intervalley canals were supplied by water from intervalley canal offtakes to supplement intravalley agricultural land area and food supplies. Areas along the Chicama-Moche Intervalley Canal exhibit many field areas of this type.

Flood Diversion Channels

Channels of this type are used at the Middle Horizon Tiwanaku Pampa Koani and Lukurmata raised-field farming areas southeast of Lake Titicaca (Fig. 1). They intercept and shunt excessive rainfall runoff from hill slopes directly into Lake Titicaca through large canal systems (Kolata & Ortloff, 1989; Ortloff, 1997; Ortloff and Kolata, 1988). While intercepted rainfall onto fields helped to provide water for the swales adjoining the raised-field mounds, excessive water input increased the swale water height beyond its useful height. Here, swales were excavated about 1 m into the groundwater level.

Hydraulic Engineering in Ancient Peru and Bolivia, Fig. 3 The Chicama-Moche Intervalley Canal and its link to the Moche Valley Vichansao Canal

Tiwanaku drainage canals with elevated outlet weirs set above the bottom of the channel directed channel floodwater above a given height over the weirs into channels draining directly into Lake Titicaca to drain flood water rapidly away to prevent amplification of groundwater and swale water height. In other words, to modulate and control the swale groundwater level with respect to raised-field mound planning surfaces, overflow weirs set a certain height above the drainage channel bottom activated when floodwater height exceeded the bottom height of the weir causing excess water to flow directly into Lake Titicaca through a channel. This arrangement served to regulate field system groundwater height by draining away excess water. Swale water height was important to provide underground water to plant root systems on field mound surfaces. Further regulation of groundwater height was controlled by aquifer seepage water flowing into drainage channels. By having the drainage channel depth intercept the top region of the groundwater aquifer, seepage aquifer water higher than the bottom depth of the drainage channel was collected and drained into Lake Titicaca. The combination of these effects maintained swale height sufficient for crop production during the rainy season. There are applications of rainfall runoff collection channels for Moquegua Valley mountain region terraces (occupied by Wari and Tiwanaku colony presence; Moseley, 2008) to divert excessive rainfall into terrace water supply canals to downhill spillage channels draining into valley-bottom fields.

Groundwater Recharging

North coast Chimu coastal *mahamaes* (sunken gardens) and Chan Chan city wells (Moseley & Deeds, 1982) were activated by irrigation canal water seepage from field plots added to the existing groundwater profile originating from sierra watershed rainfall infiltration and river water seepage as examples of Chimu groundwater recharge technology. Tiwanaku use of spring-fed canals in the Lukurmata area to deliver water to raised-field water troughs provided water with

different biochemical composition (Carney, Binford & Kolata, 1996; Ortloff, 1997, 2009) for specialty crops is a further example of groundwater recharge for a specific purpose.

Sunken Gardens, Wells, Spring Systems, and Reservoirs

Examples of sunken gardens include north coast Chimu and the earlier north and south coast societies' use of excavated pits dug to groundwater phreatic level (*mahamaes*) and pits excavated close to springs (*wacheques*) for agricultural water supply during low river runoff and drought periods (Moseley, 2008; Moseley & Deeds, 1982). Sunken pits intersecting the water table and collecting rainfall (*cochas*) operational in late post-Tiwanaku V times (Ortloff, 1997, 2009) in the Bolivian Pampa Koani area were used to support agriculture and serve as examples of last-resort water systems during drought periods. The use of wells interior to Chan Chan and located close to the coastline where the water table was close to the ground surface and whose depth could be lowered to intercept a declining water table in drought periods served as a Chimu drought defensive measure during the tenth century CE. Reservoirs penetrating groundwater level with lead-off canals to field systems sustained Supe Valley agriculture at Preceramic Caral (2500–1430 BCE) and adjacent valley sites (Ortloff & Moseley, 2012) and provided water year-round to field systems.

Runoff Interception Trenches and Runoff Canal Shunts to Rivers/Lakes/ Pools

An example of these techniques is seen in the collection and channeling of rainfall runoff flows into channels connecting directly to Lake Titicaca to limit runoff interception and seepage into groundwater to regulate local groundwater height in the swales surrounding raised-field mounds. This regulation activity controlled the height of the phreatic layer above the

groundwater layer to serve different crop types with different root system depths having different water needs. Further examples originate from the canals used to drain excess groundwater into channels to regulate moisture available for root systems in raised-field plots (Ortloff, 1997, 2009). The perimeter canal surrounding the ceremonial center of Tiwanaku (Ortloff & Janusek, 2014) served to accelerate ground drying by runoff collection and aquifer seepage to promote improved environmental conditions for city inhabitants. The Chimú used interception trenches uphill from canal systems near Farfán in the Jequetepeque Valley to intercept rainfall runoff originating from mountainous terrain (Ortloff, 1997) to direct flow into *quebradas* (flood erosion gullies) that limited damage to major canals (Ortloff, 2009).

Terrace Agriculture

Terrace (*andenes*) agriculture from post-Tiwanaku V (~1100 CE), MH highland Wari and LH Inka societies used stepped planting surfaces on mountainsides so they could move agricultural zones to higher elevations to intercept higher rainfall amounts during drought periods. The use of high-elevation canals sourced by snowmelt water during the warmer dry season and rainfall runoff water during the rainy season provided additional sources of irrigation water beyond rainy season rainfall. For situations where raised fields were flooded from high Lake Titicaca water levels (a 1.0 m lake level rise can flood upward of 120,000 ha of low-slope land bordering Lake Titicaca), the use of terrace systems provided an alternative to continue agricultural production for the Tiwanaku. The use of multi-terraced hillsides above river bottomland in the upper Supe Valley area together with spring-sourced canals irrigating field systems (Ortloff, 2009; Ortloff & Moseley, 2009) provided a defensive strategy by varying the types of agricultural systems to ensure agricultural continuity through weather/climate changes. The large population at the major Supe Valley site of Caral occupied extensive urban living areas and

Hydraulic Engineering in Ancient Peru and Bolivia,
Fig. 4 The Huaca Major at the site of Caral

multiple monumental architectural complexes (such as the Huaca Major, (Fig. 4). Their livelihood was sustained by spring-supplied canals that irrigated valley-bottom agricultural areas in conjunction with canalized spring water to terrace agricultural systems. These redundant systems maintained agricultural continuity for many centuries of valley occupation.

Specialty Sunken Gardens

These gardens were used by post-Tiwanaku V altiplano societies up to and including Inka occupation to supplement pastoralism-derived food supplies as drought extended past 1100 CE. Excavated basins (*cochas*) located near streams or in areas distant from Lake Titicaca margins where the water table remained high throughout dry periods from incoming groundwater from vast watershed areas provided a limited agricultural base to support populations after the abandonment of the city of Tiwanaku.

The Inka created large, terraced excavated pits for specialty agricultural products at Moray (Wright, McEwan, & Wright, 2006) with temperature and humidity variation to determine best growing conditions for specialty crops. Chimú *mahameas* and *wachaques* provided exploitation of local water resources largely impervious to short-term drought conditions to extend limited agricultural production of specialty crops during

drought conditions. Recent research at Tiwanaku (Ortloff & Janusek, 2014) indicates that *cochas* and variants of raised fields were integral to the urban housing areas of the city during its later phases (600–1100 CE) and had water supplies from spring-sourced canals.

Agricultural Reserve Land and Alternative Field System Following Strategy

The Tiwanaku used raised-field usage area shifts to high groundwater areas as diminishing rainfall interception and drought depressed the subsurface groundwater layer profile toward the edge of receding Lake Titicaca subject to tenth-century-CE drought conditions. Although much effort went into groundwater height control by the Tiwanaku through the use of drainage canals, long-term drought inevitably lowered the height of Lake Titicaca with a corresponding depression of the groundwater profile in areas close to the lake edge. Distant from the lake, the groundwater profile remained high from infiltrated rainfall into vast upland watershed areas in past times gradually percolating as groundwater toward the Lake Titicaca. These distant areas could be farmed in combination with *cochas* to provide limited agricultural produce to supplement livestock sources of food as drought progressed further past 1100 CE. Agricultural field area shifting allowed fallowing of nonused raised-field areas to increase later productivity during regular rainfall, non-drought conditions that prevailed for many centuries of Tiwanaku occupation of the Pampa Koani raised-field area.

Groundwater Collection into Subsurface Transport Channels Supplying Field Systems

Underground galleries penetrating the water table collected seepage water and channeled it to surface fields in the far south coast of Peru. Here, rainfall was scarce and rivers deeply downcut preventing the possibility of river-sourced

irrigation canals. Groundwater-collecting galleries built between late Nazca phases of the EIP, ca. 400–600 CE, are examples of this method (Schreiber & Rojas, 2007).

The use of canalized groundwater pools/reservoirs fed by springs was effective in mitigating short-term drought for the Supe Valley site of Caral (and other valley sites) as the groundwater table showed little variation in height throughout the year due to the large infusion of groundwater originating from mountain watershed areas percolating into the lower valley groundwater table. The Supe Valley is unique in that it maintains a high water table throughout the year and was a natural destination for Preceramic societies' taking advantage of the valley's agricultural potential. Some evidence exists that highland lakes and lagoons transferred water into Supe Valley groundwater through surface and subsurface channels.

Canal and River Water/Groundwater Seepage Utilization

An example comes from the north coast Chimú utilization of irrigation canal water seepage to recharge interior Chan Chan wells (Moseley & Deeds, 1982). This additional conservation use of water added to the existing groundwater base derived from sierra rainfall interception sources and helped maintain numerous wells within the royal compounds of Chimú capital city of Chan Chan. Moquegua Valley Chirabaya coastal groundwater seepage agriculture (Clement & Moseley, 1991) in the Ilo area of southern Peru was based on collection of deep groundwater seepage on cliff face troughs then directed by channels toward adjacent field plots. This mode of irrigation produced flows of a few liters per second and thus could only support limited agriculture. This system provided agricultural continuity through drought periods as the water table had a low subsidence rate and was able to maintain limited agriculture while surface river flow rates diminished to the point where surface irrigation was no longer possible. Some limited opportunistic north coast raised-field agriculture

at Casma, Viru, and Moche Valley coastal areas was observed as a result of amplified water table height after El Niño rains provided moist soils suitable for limited agriculture (Moore, 1988, 2000).

High Sierra Reservoir and Lagoon Water Storage for Canal Delivery to Coastal Valleys

Examples exist from high altitude (>2,000 m) Cordillera Negra mountain lagoons interconnected with canals to deliver water to highland valley and terrace agricultural systems. Water from these sources augmented groundwater levels in coastal valleys by means of water seepage through fault zones and/or percolation through bedrock-limited, shallow soil layers (Avila, 1986). The 50-km-long Hairu Catac Canal (possibly of Inka construction) irrigating the Iambe, Moro, and San Jacinto sierra areas and Nepeña Valley foothill areas are examples of this type of water storage and transfer. The probable water source supplying the Supe Valley high water table comes through geological faults transferring sierra infiltrated and runoff water to the lower coastal valley aquifer to create the high water table prevalent throughout the year that underwrote sustained canal agriculture for Caral and other Supe Valley Preceramic sites (Ortloff & Moseley, 2012).

Canal Water Collection and Diversion of Runoff to Modify Groundwater Profiles

Tiwanaku Pampa Koani used raised-field agricultural systems on the (Bolivian) Taraco Peninsula (Ortloff, 1997) to regulate water table height for different crop types with different root system moisture requirements. Rainfall runoff was collected into swales. Excessive water above the useful design level was conducted by swale connectivity to lower areas draining into Lake Titicaca and, for certain cases, excess water was conducted into adjacent canals that shunted water rapidly to the lake.

Snowmelt Water Collection Channels Directed Toward Mountainside Terraces

Examples are found in upper highland Moquegua Valley drainages in late and post-Tiwanaku V times as well as for high sierra MH Estuquiña and Wari terraces that utilized snowmelt water supplies channeled to agricultural terraces. This technique was used in elevated (or lowered) temperature periods as a water source (or water storage as ice) for terrace agriculture. Inlets to canals supplying water to lower-level terraces were relocated accordingly as the snowmelt boundary varied with precipitation, altitude, and temperature.

Vertical and Lateral Agricultural Zone Shifts

Relocation of raised-field agriculture on the margins of Lake Titicaca by the Tiwanaku to terrace agriculture on nearby hill slopes when Lake Titicaca height excursions from excessive rainfall completely covered the raised fields is an example of an agricultural zone shift. The possible reuse of very early phase MH Tiwanaku terraces during LH Inka occupation times by populations occupying mountainous and hill areas overlapping or outside of the Tiwanaku homeland area represents a strategy shift toward the use of terrace agricultural systems given the ample amount of rainfall in the altiplano environment. The presence of terraces and adjacent raised fields in close proximity to the city of Tiwanaku offered options to shift agricultural areas between Pampa Koani raised fields and highland terrace areas depending on local water table height in raised-field swales as influenced by Lake Titicaca height and groundwater arriving from distant watershed areas downslope to the lake. Lateral shifting and extension of Tiwanaku agricultural raised-field zones toward receding lake edge areas during the dry season or drought periods and expansion of raised-field areas distant from the lake edge during extended rainfall periods added flexibility to continue agriculture

to allow for changes in rainfall intensity as well as dry period duration.

Canal Intervalley and Intravalley Transport/Distribution Canals

The Chicama-Moche Intervalley Canal, the Lambeyeque-Supe-Leche Canal system, and the Lima Complex (Chillon-Rimac-Lurin Canals) (Kosok, 1965; Ortloff et al., 1985) had been used as a drought remediation measure by distributing river water from large flow rate rivers to reactivate desiccated field systems in adjacent valleys with smaller, intermittent flow rate rivers during extended drought periods. During extended wet periods, water transfer from large rivers to adjacent valley canal systems provided for extension of the growing season (Ortloff, 2009) as well as additional land areas brought into production. Intervalley canal water irrigated field systems located alongside the intervalley canal path and provided an efficient use of water close to the canal water source by limiting seepage and evaporation water losses associated with long canal paths. Long intravalley canals within the Peruvian Lambeyeque Valley (Racurumi, Taymi Canals, Kosok, 1965) served to redistribute water from rivers to field areas only reached by a separate canal dedicated to access difficult-to-reach areas.

Canal Hydraulic Efficiency Improvement Features and Flood Damage Controls

Chimu hydraulic efficiency improvements in the Chicama-Moche Intervalley Canal design came through manipulation of canal wall Manning roughness (n), bed slope (i_b), canal cross-sectional shape (hydraulic radius R_h), and canal width expansion/contraction effects on flows for subcritical and supercritical flows. Analysis of the open-channel flow hydraulic design principles used on a 1.5 km section of the canal near Quebrada de Oso (Ortloff & Moseley, 2009; Ortloff et al., 1983, 1985) indicates a knowledge base of open-channel water control principles to

achieve a canal design for a specific flow rate ($4.3 \text{ m}^3/\text{s}$) while having flow delivered to a destination location in the Froude number (Fr) range, $0.6 < Fr < 1.3$ which is close to modern practice (Morris & Wiggert, 1972). The canal exhibits, over a measured 1.5 km length, variations in n , i_b , R_h , and subcritical and supercritical contraction/expansions of canal geometry to control flow such that $0.6 < Fr < 1.3$ and maintain near-critical slope conditions to yield a flow close to unit Froude number. Thus, the canal design sustains a Froude number close to but either higher or lower than $Fr = 1$. The canal design incorporates hydraulic width contraction elements (Woodward & Posey, 1941) before the (now missing) aqueduct crossing the Quebrada de Oso that converted flow from supercritical to subcritical over the aqueduct (line G-H, Fig. 5). This velocity-reducing effect limited erosion of the fill sidewalls of the aqueduct. Further, hydraulic features of the canal (Ortloff, 2009) indicate an ingenious way to use a bound vortex resident in a concave part of the canal to effectively choke the flow and change its velocity and depth sufficient to regulate the Froude number between $0.6 < Fr < 1.3$. Flow outside of this range from El Niño runoff into the canal was then removed by side weir overflow to limit erosive flood damage. Analysis reveals that changes in i_b , n , R_h , and subcritical and supercritical Froude number effects were effectively utilized to produce a “modern” design (Ortloff, 2009).

The use of half-hexagon cross-section canal shapes for minimum flow resistance using straight-sided canal walls (Henderson, 1966; Morris & Wiggert, 1972) was demonstrated in the Pampa Huanchaco canal system (Ortloff et al., 1982, 1985). The use of stream-wise canal shape changes to regulate water height to activate overflow weirs served to limit El Niño flood damage; examples of this design feature are found in Jequetepeque Valley canals and the Chicama-Moche Intervalley Canal. The use of a choke (contraction section) in a canal to allow a given design-maximum flow rate to pass through the choke (at $Fr = 1$) causes a water height change upstream of the choke for any excess flow rate over the maximum allowable

Hydraulic Engineering in Ancient Peru and Bolivia, Fig. 5 Plot (Woodward & Posey, 1941) of $Fr_1^2/2$ (incoming flow to channel width contraction – vertical axis) versus $Fr_2^2/2$ (outgoing flow from contracted channel). Line G-H represents the path from an incoming flow with $Fr_1 = 3.0$ to an outgoing flow with $Fr_2 = 0.19$ due to a width contraction ratio $W_2/W_1 = 0.65$. The transition

from a supercritical $Fr_1 = 3$ to subcritical $Fr_2 = 0.19$ occurs through a hydraulic jump. Regions labeled C represent channel contraction effects; regions labeled E represent channel expansion effects – note the difference in expansion/contraction effects for different incoming flow subcritical or supercritical Froude numbers

design flow rate. The excess high height flow then activates an elevated side weir eliminating and directing the flow to a lower drainage area.

A further example of flow control derives from changes to existing canal designs related to lowering seepage and evaporation losses for long-length transport canals. A canal lining or letting impervious silt accumulate on canal bottoms sometimes accomplishes this. For the Chicama-Moche Intervalley Canal, a constant slope, contour canal segment entering and making a U-shaped path along the walls of a deep interior valley was seen to be later replaced by a short, straight aqueduct joining the entry and exit points to the deep valley. The shortened

aqueduct canal path lessened the length of the canal by about 1.0 km thus reducing flow resistance, seepage from the canal bed, and evaporation water loss.

Lomas Farming

This type of farming derives from coastal fog condensation water supply to lichen pastures on Peruvian north central coast areas. Winter fog (*garua*) condensation starts lichen growth; this begins the food chain starting with snails using the lichen as a food source which is then followed by predator species feeding on lower life forms in

the chain. This attraction served local residents of the area by providing a food source composed of larger predator species drawn to the area for its diversity of plant and animal life. While the lomas systems were utilized in the early Formative Period to provide agricultural plant products as well as edible protein sources (Lanning, 1967), the degree to which human intervention prevailed to control and amplify its potential as a food production area remains a research topic.

Adoptions Toward a Marine Resource Base

For drought-affected coastal regions with access to marine resources (fish, shellfish, edible aquatic plants), emphasis on exploiting marine resources provided a protein supplement to plant carbohydrate food supplies. Several Peruvian north central coast Preceramic societies organized valley sites with coastal villages providing marine resources and inland sites largely invested in industrial and comestible crop production. Trade between coastal and inland sites formed a cooperative economic model seen in the Supe Valley and to a lesser degree, in adjoining north central coast societies (Ortloff & Moseley, 2009; Sandweiss, Shady-Solís, Moseley, Keefer, & Ortloff, 2009; Shady, 2000, 2009). While this cooperative model served well to provide a balanced carbohydrate and protein diet, later coastal societies resorted more heavily to exploiting marine resources during drought periods when water supplies were insufficient for agriculture.

Adaption Toward Sierra Pastoralism

As a tenth-century CE highland drought response, a shift from agriculture (due to recession of groundwater in raised-field swales) toward herding and pastoralism occurred. This emphasis on alpaca, llama, and vicuña herding was possible due to well-watered highland grassland pasture areas (*puna*) prevalent at high altitude; snowmelt water provided

supplemental water to augment rainfall. This shift to pastoralism provided a protein food source to augment produce from drought-affected raised-field and terrace areas. In many cases (Murra, 1972), major highland societies maintained colonies in different ecological zones that were able to export food varieties back to homeland areas to maintain their viability during both normal rainfall periods and drought. While partially effective in supplying cities with imported food items, this means of support was marginal to support large populations, and as drought intensified, spatially distributed colonies in different ecological zones also suffered from drought and were unable to provide an adequate support base for their homeland cities.

Raised Fields

Examples from the Bolivian altiplano from the MH Tiwanaku society are low-vulnerability agricultural systems largely resistant to short-term drought due to the continuous arrival of groundwater from watershed zones distant from Lake Titicaca combined with slow groundwater subsidence from surface evaporation. These fields originate about 600 CE and excavations to 2 m depth show that experimentation took place to decide the best geometric design of ridges and swales for maximum agricultural productivity and heat storage capability. Earlier versions had short wavelengths between ridges than those observed in later-phase constructions. Raised fields are constructed by excavating swale trenches deeper than groundwater level so that the swales contain groundwater. Excavated soil is mounded between swales to form planting surfaces. Typically raised-field mound widths vary in the 4–10 m range and lengths from 10 to 100 m; mound heights are usually 1 to 2 m above the swale water surface, and swale depths are on the order 1 m. Raised fields are able to store heat from the sun during the day to prevent freezing of root crops during cold altiplano nights (Kolata & Ortloff, 1989, 1996) thus preserving crop spoilage from freezing.

City Environmental Control Through the Use of Drainage “Moats” to Accelerate Ground Drying and Regulate the Deep Groundwater Profiles for Monument Foundation Stability

A depressed, encompassing channel “moat” surrounding the ceremonial center at the city of Tiwanaku collected rainfall runoff and seepage from groundwater layers to promote rapid soil drying throughout rainy and dry seasons thus improving environmental living conditions for city inhabitants. By aquifer seepage into the “moat” during both wet and dry seasons and water supply through a moat-intersecting canal fed by distant springs, deep groundwater levels were stabilized throughout seasonal weather cycles. The year-round stabilization of the deep groundwater level by maintaining the same saturated aquifer water content prevented deep aquifer dry out and collapse which had the beneficial effect of maintaining the bearing strength of foundation soils underlying large monumental structures within the moat boundary thus reducing their settling and deformation (Ortloff & Janusek, 2014).

Hydraulic Jump Control

An example of MH Tiwanaku water engineering utilizing hydraulic jump control comes from the Lukurmata area north of Tiwanaku city. Rainfall runoff collected into a steep, unlined channel flows into Lake Titicaca bypassing a temple to protect it from flood damage. As lake height is high during the rainy season, the intersection of a high-velocity, supercritical channel flow with still lake edge water produces a large, turbulent hydraulic jump eroding the outlet in the upstream direction. To avoid upstream migration of the hydraulic jump and erosion of the fill channel, Tiwanaku hydraulic engineers skillfully vary channel outlet geometry to essentially produce a hydraulic jump of zero height thus canceling the jump (Kolata & Ortloff, 1989; Ortloff, 2009). Open-channel flow engineering in the Chicama-Moche Intervalley Canal and the Jequetepeque

Canal demonstrates that water engineers knew how to create hydraulic jumps to transition flow from supercritical to subcritical flow to avoid canal erosion and to locally elevate water to activate side weirs for the same end (Ortloff, 2009).

The adaptive strategies shown in Table 1 indicate conscious effort by different societies to control water supplies using a variety of engineering technologies specific to different geographic locations and agricultural systems in different time periods. While water engineering improvements and delivery efficiency improvements accompanied long-term favorable climate trends, other engineering responses provided defense measures against El Niño flooding and drought. For changes in weather and climate affecting agricultural productivity, additional responses in the form of modifications to existing systems or in more dire circumstances, design and building of intervalley canal systems to bring additional water supplies to homeland areas proved the only solution. The responses listed in Table 1 required long-term observation and recording of weather and climate patterns and changes in climate that portended future disaster unless large-scale measures were put into place to counteract decreases in water supply. Once recognition of threats to food supply were confirmed by trends over time, perhaps a leadership plan evolved to organize key decision-makers to discuss technical planning to ameliorate crises affecting the well-being of their society. Further logistics to recruit labor and provide material and rations for extended field operations were planned to perform required tasks. The inception and construction of the Chicama-Moche Intervalley Canal as a drought remediation measure fits well into this category.

Table 1 provides a library of agro-engineering responses to long- and short-term climate and weather variations over many time periods and demonstrates that climate and technology development were important factors in design, operation, administrative planning, and construction to ensure sustainability of agricultural fields vital for societal survival. While many of the technology advancements listed came from response to agricultural threats, many listings were technical

improvements used to increase irrigation water flow rates to fields and/or reduce water seepage and evaporation losses by canal redesign and relocation all to improve agricultural yields. In totality, the listings indicate an active and creative engineering mentality in Andean societies to conceptualize an irrigation system design suitable to environmental and water availability conditions, put plans into practice by organizing construction labor, maintaining its operation by experienced farming personnel, and finally, to improve its operational efficiency over time by observance of its performance and instigating appropriate engineering redesigns.

Water Infrastructure of Petra

To begin the discussion of Nabataean water system development and its progress toward utilizing all possible resources to meet increasing population demands, solid and dashed lines of

Fig. 1 detail the supply and distribution pipeline system leading water into the urban core of Petra. Numbered locations denote the major buildings, temples, and site features listed in the figure legend. Shown are major dams (-d), cisterns (c), water distribution tanks (T), and springs (s). The (-d) dams located across streambeds (*wadis*) are barrier structures built to hold larger quantities of water for redistribution to urban structures or localized agricultural areas. Dams denoted (d) are minor catchment structures that stored water in mountainous areas to prevent its descent to the Petra basin and/or have channels leading water to lower-level cisterns. The superimposed grid system (A, B, C; 1, 2, 3) defines a coordinate system of 1.0 km² grid boxes to enable the location of features listed in the figure legend. Figure 1 represents the present state of discovery of pipelines incorporating logical connections and joining structures extrapolated from existing pipeline segments. Due to degradations from man and nature over 2,000 years, some pipeline sections are now missing from their original holding troughs or obscured by subterranean placements (or yet to be discovered in their entirety) requiring extrapolation between available visible parts to represent the pipeline paths shown in the figure. With further research and excavation, more details will undoubtedly come to light; as such, Fig. 1 represents the current state of research (Bellwald 1995, 2008) and is, at best, a first approximation to the entirety of the total pipeline water system.

Petra's urban core lies in a valley surrounded by rugged mountainous terrain; seasonal rainfall runoff passes into the valley through many streambeds and drains out primarily through the Wadi Siyagh (Fig. 1, A2). The main water flow into the city in ancient times originated from rainfall runoff from Wadi El-Jee to the north, Wadi Al Hudayb to the south, and from the watershed area supplying runoff into the Wadi Mousa streambed; combined surface flows from these sources passed through the Siq (Fig. 1: D1 to C1). By later first century CE construction of a diversion dam and tunnel (8, Fig. 1), water was deflected from the Siq entrance and led to Wadi Mataha (Fig. 1, C-2, 3) that linked up with the

Hydraulic Engineering in Petra, Fig. 1 (continued)

section of the Wadi Mousa streambed within the city center and drained water into the Wadi Siyagh (Fig. 1, A-2). Runoff water from southern sector Wadis Thughra, Nmeir, and Farasa and northern sector Wadis Nharareeb, Kharareeb, Ma'Aiserat, and Turkamanya (Fig. 1) drained runoff into the lower-level Wadi Siyagh away from the city center (Bellwald, al-Huneidi, Salihi, & Naser, 2003). The Siq is a natural divide through the Jebel el Khubtha mountain range whose narrow passageway ranges from 5 to 10 m in width; the north and south walls of the Siq are near vertical and have heights up to 80 m (Fig. 2). Early water supplies to the city in the first and second centuries BCE were through a slab-covered, open channel dug into the floor of the Siq conducting water from the distant Ain Mousa spring into the urban center of the city as far as Hadrian's Gate (43, Fig. 1). Later first- and second-century CE builders abandoned this supply system and replaced it with a long pipeline carrying water from the Ain Mousa spring along the Colonnade Street (Cardo) (23, Fig. 1). Later century construction (Ortloff & Crouch, 2003) revealed an integrated approach to site water system management demonstrated by new and novel features:

1. Surface cisterns to capture rainfall runoff (Fig. 3)
2. Deep underground cisterns (one located in the eastern part of the Great Temple) (28, Fig. 1)

3. Multiple pipeline systems sourced by springs and storage reservoirs
4. Floodwater control through diversion dams and tunnels
5. Pipeline supply system redundancy to ensure water delivery from multiple spring and reservoir sources to high population concentration parts of the city (marketplace and theater) (Fig. 12)
6. Pipeline sand-particle filtration and removal basins (primarily in the Siq)

These later modifications reflected the need to bring high-quality potable water reliably into the city center area and to serve hillside occupation zones above the valley floor. Since the early lowest-level Siq open-channel delivery was located on the Siq floor, its ability to supply water to higher outlying city zones was limited. Here population expansion and the requirement for water to higher elevation parts of the city required higher-level Siq pipeline systems. All these later changes demonstrated the continual evolution of the Petra water system through time and reflect the application of acquired technologies from archaic and/or exterior sources integrated with indigenous hydraulic innovations, to provide for the increasing water needs of the city.

The means to capture and store a fraction of rainfall runoff through dams and cisterns, to build

flood control systems and build pipelines and channels to deliver water from distant springs, and to manage these assets to provide a year-round water supply to the city is key to

Hydraulic Engineering in Petra, Fig. 2 View of the narrow Siq entry path into the inner city (10, Figure 1)

understanding Nabataean contributions to hydraulic science and water management practices. While water storage was a partial key to the city's survival, springs internal and external to the city (Fig. 1: Ain Mousa, Ain Umm Sar'ab, Ain Braq, Ain Dibdiba, Ain Ammon, Ain Beidha, and Ain Bebdhehbeh) supplied water channeled and/or piped into the city to provide the main water supply. While the Ain Mousa spring was the main water supply to Siq pipelines, only $40 \text{ m}^3/\text{h}$ was used for this pipeline. Higher spring output levels were used to charge several reservoirs above the city to maintain a backup water supply in case of drought and increased water demands from arriving trade-mission caravans or special ceremonial gatherings that necessitated a sudden increase in water demand. Of all these springs, the Wadi Siyagh spring near the quarry (Fig. 1, 31) is still functional and used by local inhabitants, while all others are currently dry and abandoned. The Ain Mousa spring now provides water for the modern town of Wadi Mousa as well as for religious ceremonies given its historical Biblical and Koranic associations. The upper reaches of Ain Braq water system (Fig. 1) consists of a trough cut into bedrock (Fig. 11) that supported a continuous pipeline at one time. Its continuance to the plateau north of Wadi Farasa (Fig. 1) to supply the Zhantur housing area (Fig. 1, 61) and a cistern (Fig. 8) near the housing area had a pressurized siphon pipeline section to

Hydraulic Engineering in Petra, Fig. 3 Typical water storage cistern found in B-2 sector of Figure 1

achieve water transit through a depressed valley area (Oleson, 1995, 2007). If earlier versions of the Ain Braq water conveyance system consisted of slab-covered, open trough sections that were sealed to limit evaporation and soil intrusion, then this portion of the conveyance system served as an effective, exterior-sealed “pipeline” subject to similar hydraulic principles governing either full or partial flow in terra-cotta pipelines. Figure 8 illustrates that circular cross-sectional terra-cotta pipelines associated with the Ain Braq system were buried about 1.0 m under the ground surface and led water to a cistern near the pipeline branch to the Zhanthur housing district. Given the preponderance of pipeline sections of this system, it is likely that the entire system contained a continuous pipeline from the spring source. Figures 9 and 10 show (unexcavated) surface traces of water distribution features leading to this area. Notably, a quote from the ancient Greek historian Strabo “. . .and the inside part of the city having springs in abundance, both for domestic purposes and for watering gardens. . .” reaffirms that springs were a vital part of the water resources of the city. Additionally, spring-supplied reservoirs (Fig. 1; Zurraba, 1), many of which are now destroyed by recent town construction, served to supply lower-level fountains and storage facilities to provide water on demand through pipelines.

Water Management of the Siq Pipeline System

The main city water supply originated from the Ain Mousa spring about 7 km east of the town of Wadi Mousa (Fig. 1, D1) and was combined with the waters from the minor Ain Umm Sar’ab spring. Because the flood bypass tunnel at the Siq entrance and infilling and paving of the Siq floor in ancient times reduced flood episodes, parts of the early slab-covered, open channel lie under the pavement surface attributed to Aretas IV and later Roman (and modern) constructions. Recent excavations reveal ~5 m of flood debris coverage over the original paved area in front of the Treasury (Fig. 1, 11) and water basins

connected to the original open-channel water supply system. With increasing water needs for an increasing population in early centuries CE, an elevated 2 km long, north-side “Little Siq” pipeline extension (Fig. 6) completes the totality of the Siq pipeline system (Ortloff, 2005, 2009) to supply potable water to further reaches of the urban core of Petra utilizing a large fraction of the Ain Mousa spring flow. Owing to destructive hydraulic instabilities (water hammer, transient pressure waves, flow intermittency, internal pipeline hydraulic jumps, turbulent drag amplification zones, vapor pockets) that occur in pipelines, a new set of hydraulic and water management problems in design of the system required the development of new technologies to manage stable pipeline flows, match part of the Ain Mousa spring output to the maximum flow rate the pipeline could sustain, and limit pressure within the pipeline to avoid leakage at the many thousand pipe-joint connections along the length of the pipeline. Here for a pipe element length of ~0.35 m and total pipeline length over ~10 km with a total height drop of over ~50 m, high hydrostatic pressure in a full-flow pipeline would increase the likelihood of leakage. The solutions to mitigate all these design and operational problems provide insight to Nabataean water management expertise.

CFD calculation (FLOW-3D 2013) of maximum flow rates (m^3/s) in long 14 cm diameter piping at 2, 4, and 6° slopes for 1.0 and 3.0 m head (height of water in a tank above the entrance to piping) reveals that past 300–400 m, an increase of input head does not substantially increase the flow rate (Fig. 4). This result, noted in antiquity by Archimedes, essentially means that the flow rate due to cumulative water-pipeline internal wall shear resistance limits the flow rate the pipeline allows. In other terms, a pressure gradient is required to produce a given pipeline flow rate; with higher flow rates and longer pipe lengths comes more shear resistance requiring a higher pressure gradient to overcome. Past about 300–400 m, even a 3X head increase is insufficient to increase flow rate. The implication for the Siq pipeline is that only a fraction of the Ain Mousa spring output ($500 \text{ m}^3/\text{day}$ according to

Hydraulic Engineering in Petra, Fig. 4 Allowable flow rate diagram for 18 cm diameter piping for 2, 4 and 6 degree piping declination slopes for 1 and 3 m water

height (head) values. Results indicate that past ~400 m piping lengths, additional head does not significantly increase flow rate

Hydraulic Engineering in Petra, Fig. 5 Typical head reset basin between sequential piping lengths along the Siq pipeline

Oleson 1995, 2007) can be transmitted through the 14 cm diameter pipeline under full-flow conditions due to the pipeline's cumulative flow resistance associated with its ~10 km length. Given this challenge, Nabataean water engineers devised the perfect solution. Along the length of the north-side pipeline, several open basin features (Fig. 5) are found at ~400 m intervals along the pipeline. Each basin permits the accumulation of water serving as a “head tank” for the

downstream ~400 m piping length. Essentially, the head is reset at the origin of each ~400 m piping length so that flow through that segment is sensitive to this supply head value according to Fig. 4 results. The open basins additionally served as drinking basins along the Siq path and provided easy cleaning of any soil particles that accompanied flow from the Ain Mousa spring. The presence of open basins negates the assumption that the piping supported pressurized full

Hydraulic Engineering in Petra, Fig. 6 Remaining pipeline elements in the elevated Little Siq extension past the North Siq pipeline indicated by dashed line (Sector 1, B-C in Figure 1)

H

flow, and because of the open basins, flow in the pipeline is partial flow sustaining an airspace above the water surface at atmospheric pressure, thus eliminating pipe-joint leaking that would occur from pressurized, full-flow conditions. To achieve a piping design based on 14 cm pipe diameter at the floor angle of the Siq when the Siq pipeline was constructed (the piping runs parallel to this angle), ideally partial, critical flow at unit Froude number (Fr) at the critical depth provides the maximum flow rate the piping can convey. As open basins were sequentially lower than their predecessor basins due to the declination slope of the pipeline, water height in a basin supplied the head for its adjoining downstream piping section, and partial flow can be retained throughout the piping sections with a flow height close to the critical depth. In the “Little Siq” area immediately west of the Treasury, a lower-level pipeline appears close to present ground level; this trough would be about 5 m above the original pavement level now obscured by flood debris infilling. Another pipeline appears about 10 m above this pipeline (Fig. 6), and as it runs at a higher elevation, it provides water to further reaches of the city. This higher elevation pipeline section continues the Siq pipeline and is set at a lower angle than the Siq pipeline. Given the (accepted) 40 m³/h Ain Mousa flow rate, a further consideration arises as to the stability of the flow in the piping sections within the Siq as

well as for water arriving to the Nymphaeum (Fig. 1, 42) through the continuation of “Little Siq” pipeline. Here if flow delivery is pulsating into open basins, then spillage and sloshing occurs in the basins amplifying the flow instabilities transmitted along successive piping lengths. Without stable pipeline flow, water transfer in the Siq and continued piping to the Nymphaeum are inoperable due to spillage flow losses and pulsating delivery flow rates; these would all be inconsistent with a competent engineering design expected to be found at a world-class city.

For an examination of flow stability, three-dimensional computer models (FLOW-3D 2013) were made for a 1,220 m long section of the 14.0 cm diameter piping used in the “Little Siq” extension with a declination slope slightly less than that found in the Siq pipeline. This length represents the distance from the exit of the Siq pipeline to the Nymphaeum water destination location. Computer solutions for 0.305 (A), 0.610 (B), 1.54 (C), and 3.05 (E) m/s water velocity were made assuming full-flow entry conditions at the right boundary with wall roughness typical of the interior surface of the piping elements (Fig. 7). Figure 7 (D) results are for a smooth interior pipe element wall at 1.54 m/s velocity to demonstrate the effect of wall roughness on flow patterns at the same water velocity. From the prior result of 40 m³/h accepted into the Siq piping, average pipeline water velocity is on

Hydraulic Engineering in Petra, Fig. 7 Flow stability diagrams indicating internal partial flow, water flow patterns in the Little Siq pipeline for various flow rate conditions

Hydraulic Engineering in Petra, Fig. 8

Recently discovered subterranean pipeline-cistern component of the Ain Braq siphon system (Sectors 1-2, B in Figure 1) delivering water to the Zanthur housing district, Great Temple and Paradeisos (Bedal 2004) districts (2-B in Figure 1).

H

Hydraulic Engineering in Petra, Fig. 9 Surface traces of one of the branches of the subterranean piping channel leading water to the Zanthur housing district (Sector 2-B in Figure 1)

the order of 0.7 m/s. Given that the flow is slightly supercritical ($Fr \approx 1.18$) at this velocity on a hydraulically mild slope, the flow will approach a normal depth (Morris & Wiggert, 1972) for cases (B), (C), and (D) appropriate to each velocity. For flows close to critical, the normal depth is close to the critical depth. Figure 7 shows transition to lower water depths from the initial full-flow boundary condition for all supercritical (B), (C), (E), and (D) cases; for the subcritical case (A), water is at a low level due to the low flow rate and flow velocity. Figure 7 (B) at 0.610 m/s is close to the mean velocity of 0.71 m/s and indicates that only minor, random height excursions occur in the flowing water within the pipeline. This indicates that the water supply system through the Siq to the Nymphaeum is stable. At twice the velocity, Fig. 7 (C) indicates large height fluctuations in the water surface that indicate unstable flow pulsations occur throughout the pipeline system. This indicates that the flow rate selected from the Ain Mousa spring was a deliberate design choice to achieve stable flow in the system. Comparison of Fig. 7 (C) to (D) indicates that internal pipeline wall roughness amplifies large-scale turbulent eddies that contribute to flow unsteadiness; this effect is included in the (B) results. Tracking the end

Hydraulic Engineering in Petra, Fig. 10 Traces of the reservoir tank supplied by the Ain Braq siphon that divided water flow into two discrete piping systems—one directed toward the Zanthur housing district and the other toward the Great Temple (Sector 2-B in Figure 1)

part of the “Little Siq” pipeline reveals it is connected to an open basin indicating a further feature to ensure flow stability for flow into further pipeline branches. While a branch of this pipeline delivers water to the Nymphaeum, another branch likely crossed the Wadi Mousa streambed by a bridge to deliver water into the south marketplace area on the Cardo. This reinforces the observation that redundant water flow paths existed to provide water to key facilities located at, or near to, the marketplace so that water supplies were guaranteed if one of the branches was not serviceable for repairs or cleaning (Ortloff 2005). This redundancy also holds for the Wadi Mataha pipeline as a branch from 22 to 42 (Fig. 1) provides water to the Nymphaeum and marketplace as well as

Hydraulic Engineering in Petra, Fig. 11 Part of the Ain Braq channel (Sector B-1 in Figure 1) that originally supported a pipeline from a distant spring to the siphon that led water through system components shown in Figures 8–10.

supplemental water supplies to the Theater district (Figure 12) by a bridge-pipeline continuation across the Wadi Musa streambed.

Conclusions

Analysis of the Siq water supply system indicates that its design, function, and management had been carefully crafted to eliminate potential water instability effects that promote leakage and open basin spillage while providing $40 \text{ m}^3/\text{h}$ water into the city interior. The pipeline system was crafted to supply this flow rate as the maximum value the pipeline could transport further implying Nabataean knowledge of high levels of hydraulic science only formulated in western

H

Hydraulic Engineering in Petra, Fig. 12 The Petra Theater (19, Figure 1). Water supplied to the Theater district originates from a Siq south branch pipeline

extension, a bridge-pipeline extension of the Wadi Mataha pipeline (Sector C–2 in Figure 1) and (possibly) a supplementary branch off from the Ain Braq pipeline.

science years later. Avoidance of flow instability problems by using advanced hydraulic designs found throughout the Siq pipeline system decreases water management problems significantly and decreases maintenance (except for unavoidable accumulation of calcium carbonate “sinter” choking the interior diameter of the pipeline that later required the removal of top parts of the pipeline to restore system functionality at reduced flow rates). Thus water management became routine over long time periods as high levels of technology initially incorporated into the Siq system design eliminated many problems requiring maintenance were a less-efficient design in place. A similar design stratagem underlies modern water delivery systems dependent solely upon gravity for water transport. For Petra, similar design considerations are unique in their foresight of a hydraulic technology only formalized in western hydraulic science some 2,000 years later.

Hydraulic Systems in the Middle East

Tony J. Wilkinson and Louise Rayne

Durham University, Durham, UK

Introduction

Because of its arid climate, much of the Middle East benefits from the development of water management systems: without water to supplement the meager rainfall, agriculture and permanent settlement would be impossible in many places. However, aridity is not the only factor in making the land habitable, and in this entry, we demonstrate that water supply systems have progressively spread from drier areas to eventually develop in wetter parts of the region. This is for reasons other than to combat water deficits. Consequently in this entry, a distinction is made between those water systems that were used to address water deficits (whether for irrigation, drinking water, or for other purposes) and those that were mainly intended to stabilize cropping or intensify yields.

Both domestic water supply and the delivery of water for the irrigation of crops are summarized for the entire Middle East (Fig. 1: location 1). Whereas a number of recent volumes have tackled the history and technology of

water use (Amit, Patrich, & Hirschfeld, 2002; Biernert & Häser, 2004; Hodge, 1991; Wikander, 2000), this entry will complement these approaches by also focusing on the landscape setting of ancient water systems.

Climate, Environmental Change, and Water Supply

As Fig. 2 indicates (For data see: Schneider, Becker, Meyer-Christoffer, & Ziese, 2011), rainfall averages in the northern Fertile Crescent today are low. Much of Mesopotamia receives below 200 mm per annum, which approximates to the limit of rain-fed agriculture. The core area of southern Mesopotamia is famous for the precocious development of cities in the fourth and third millennium BC, whereas north of this arid riverine desert, agriculture can survive from rainfall alone. In addition, the deserts of Arabia and Iran provide examples of early water management, which have been discovered, in part, because once built, an installation will remain in place because there has been little subsequent activity to remove it. Such “landscapes of survival” have supplied us with some of the earliest evidence of hydraulic management. Additionally throughout the Middle East, smaller rivers, ephemeral wadis or streambeds, surface runoff, and groundwater extraction all have become more significant for water supply.

Numerous studies demonstrate that during the earlier part of the Holocene (roughly 10,000–6,000 years ago), the region was significantly moister than during the last 4,000 years. Although these changes were not necessarily synchronous over the entire Middle East, it is evident that development of irrigation and water supply technology often occurred when the climate was becoming, or had become, significantly drier.

Although water management systems developed during the earlier moister phases of the Holocene there was a significant increase in their use during the last 4,000 years. However, at the same time as the climate was becoming drier, in parts of the Middle East, human

Numbered locations: (1) Southern Mesopotamia, Iraq; (2) Buraimi, United Arab Emirates; (3) Khabur Basin, Syrian Arab Republic; (4) Amuq, Turkey; (5) Ghab, Syrian Arab Republic; (6) Balikh Valley, Syrian Arab Republic; (7) Wadi Jizzi, Oman; (8) Khirbet ez-Zeraqon, Jordan; (9) Troy, Turkey; (10) Karun River, Islamic Republic of Iran; (11) Gorgan River, Islamic Republic of Iran; (12) Northern Negev desert, Israel; (13) Sadd el-Kafara, Egypt; (14) Kissonerga-Mylouthkia,

Cyprus; (15) Wadi Abu Tulayha, Jordan; (16) Choga Mami, Iraq; (17) Tepe Yahya, Islamic Republic of Iran; (18) Tepe Pardis, Islamic Republic of Iran; (19) Tell Oueli, Iraq; (20) Byblos, Lebanon; (21) Al-Rawda, Syrian Arab Republic; (22) Kurban Hoyuk, Turkey; (23) Mari, Syrian Arab Republic; (24) Bāt, Oman; (25) Balis, Syrian Arab Republic; (26) Dhamar, Yemen; (27) Marib, Yemen; (28) Urartu, Turkey; (29) Kar Tikulti-Ninurta, Iraq; (30) Nineveh, Iraq; (31) Carchemish: Turkey and Syrian Arab Republic; (32) Siraf, Islamic Republic of Iran; (33) Sohar, Oman; (34) Mecca, Saudi Arabia

populations were increasing, political economies were becoming more complex, and cities were larger. By the first millennium BC, the area was witnessing the growth of massive territorial empires and their associated capitals, which provided the administrative context for creating some of the more sophisticated systems of water supply.

However, the development of such systems also resulted in unanticipated environmental

consequences. For example, excessive irrigation and the accumulation of outflow waters resulted in waterlogging and the development of marshes, such as in the Amuq and Ghab Valleys of Syria and Turkey (Fig. 1: locations 4 and 5), as well as in southern Mesopotamia (Cole, 1994). Elsewhere, the discharge of minor rivers, such as the Balikh, apparently was depleted by the excessive withdrawal of water for irrigation (Fig. 1: location 6).

Hydraulic Systems in the Middle East, Fig. 2 The rain-fed and irrigated zones of the northern Fertile Crescent in relation to modern rainfall

Archaeological Evidence for Ancient Water Systems

Although ancient water supply channels can be long and robust features, their frequent construction within riverine environments that are subject to both erosion and sedimentation can result in canals being eroded away or obscured by sediments.

Field evidence generally consists of visible channels, some of which have upcast banks created during construction and canal cleaning (Wilkinson, 2003). Larger-scale irrigation systems will include intake structures such as a dam and reservoir, abstracting from a perennial water source, as well as a main transport canal. Sequences of offtakes will branch off from this and divert water into the fields. Often, however, only the main canal will be preserved.

Archaeological survey enables irrigation systems to be located and recorded, dating material to be collected and other contextual information to be identified. Excavation is often necessary for

absolute dating and for determining the dimensions of the original, non-eroded/silted canal. These parameters can indicate the amount of water which could flow through the system.

Remote sensing has offered new ways of recording water management features relatively quickly and cheaply and has the advantage of identifying water supply channels over large areas. Data employed includes recent high-resolution imagery such as DigitalGlobe, but declassified CORONA satellite images from the 1960s and 1970s have proved especially useful because they were taken before much destruction of the modern landscape had occurred (Ur, 2005; Fig. 3).

Dating Evidence

Critical to the development of any history of water supply is the date of the features themselves. Dating evidence can be gained through excavation and survey and by the association of canals with dated archaeological sites. Excavated sections in canals can provide material for

Hydraulic Systems in the Middle East,

Fig. 3 Satellite image of canal, the Band-e Valī, linking the Gorgan River with the Sasanian (fifth–sixth century AD) Gorgan Wall and ditch in northeastern Iran (CORONA satellite image courtesy of US Geological Survey; from Sauer, Rekavandi, Wilkinson, & Nokandeh, 2013, Fig. 3:61)

Hydraulic Systems in the Middle East, Fig. 4 Post-Abbasid canal cutting the Abbasid site of Heraqlah, near Raqqa, Syria

absolute dating. Archaeological surveys have also facilitated dating through analysis of surface scatters of material alongside canals (Geyer & Monchambert, 2003; Kuhne, 1990). In some cases evidence is provided by written material, such as inscriptions associated with Assyrian canals in Northern Iraq (Bagg, 2000b; Jacobsen & Lloyd, 1935). Perhaps the most significant development in recent years is the use of optically stimulated luminescence dating (OSL), which can provide date estimates for quartz or feldspar grains in canals and their upcast.

In some cases a feature of unknown date can be dated based on an association with features of known date. Irrigation channels around the

Abbasid site of Heraqlah to the east of Raqqa in northern Syria provide an example of the sequence of “layers” which these systems can form in the landscape. The CORONA image (Fig. 4) shows a large canal cutting through the walls of the Abbasid site of Heraqlah, therefore demonstrating that the canal itself postdates the early Abbasid period.

Nevertheless, many irrigation features are multi-period networks. Canals can have lifetimes which involve construction, use, abandonment, and later modification/reuse. For example, the sustainability of many ancient systems in the landscape is demonstrated by ancient (Assyrian–Early Islamic) systems which

Hydraulic Systems in the Middle East,

Fig. 5 Travertine-encrusted conduits of Late Antique date at Pamukkale, Turkey

persisted into the early twentieth century AD, as was the case for many canals alongside the Euphrates, Balikh, and Khabur Rivers.

Classification of Water Supply Systems in the Middle East

The recognition of ancient water supply systems by survey or by remote sensing depends upon the existence of diagnostic features that correspond to some of the main classes of those systems. In the Middle East, such diagnostic features also provide evidence of how the technology of water supply developed; they fall into the following broadclasses.

Groundwater Supply

Diagnostic features of wells and water holes include rings of soil and gravel accumulated around the mouth of the well. Wells are usually only capable of supplying sufficient water for a household or small garden but have the advantage of being built and maintained at the household level (Costa & Wilkinson, 1987, pp. 43–53; Hodge, 2000b, p. 33).

Qanats are dug to intercept groundwater (or underground springs) and then lead the water away via a gently sloping tunnel to a settlement and its fields beyond. Following the excavation of the “mother well,” which is the prime

water-gathering point near the water source, the qanat is usually dug from the dry downstream part of the qanat just above the settlement to intersect with the mother well via an underground tunnel (Beaumont, 1989; English, 1998).

Perennial Surface Water Supply Channels

The tapping of water from springs or pools in wadi beds (known as *ghayl* irrigation in much of Arabia) has long been a fundamental form of water supply and in Oman is a technique that extends back to the third millennium BC (Cleuziou & Tosi, 2007). These small, relatively stable flows are usually accommodated within open channels that by the Roman–Parthian period (ca. first/second century BC to third/fourth century AD) could extend up to 40 km in length and were usually lined with hydraulic plaster, although in some locations they have become coated by deposits of natural travertines (Fig. 5). In some cases rock-cut conduits and tunnels were also used to transport water from springs or streams.

In contrast, large open earth-lined channels that diverted water from perennial rivers are characteristic of the Tigris and Euphrates Rivers and their tributaries, as well as other major perennial river systems such as the Orontes, Khabur, Karun, and Gorgan Rivers (Fig. 1, locations 5, 10, and 11 and Fig. 4). Such systems consist

of (1) a water-gathering zone near the source river, (2) a transportation zone that conducted the water, and (3) the settlement and its fields where the water was consumed (Wilkinson, 2003, pp. 47–50).

Episodic Surface Water Supply

Whereas perennial rivers produce an annual flood that can be managed, the utilization of floodwaters incurs higher risk and requires the incorporation of some form of safety net to evacuate excess water. Flood irrigation consists of a suite of technologies based around a continuum of processes. At the largest scale, flood irrigation from rivers is usually termed *sayl* irrigation (see Varisco (1983) for the distinction between Arabic *sayl* and *ghayl*). On the other hand at a small scale, runoff can simply be gathered from the slope above a field and directed to the land to supplement the local rainfall. The fundamental principle underlying the gathering of water from ephemeral flow is the distinction between the contributory runoff area and the recipient or run-on area, usually a field or system of fields (Pacey & Cullis, 1986). In the case of flood irrigation, the contributory area can consist of an entire river basin, whereas local runoff systems may make do with the runoff from a small patch of ground immediately upslope of the recipient field (Wilkinson, 2006). The classic case study of runoff technology was made in the northern Negev Desert where Roman and Byzantine runoff agriculture formed the economic mainstay of farmsteads, villages, and small towns along the desert margins (Fig. 1: location 12; Bruins, 1986; Evenari, Shanan, & Tadmor, 1982).

In addition, water tanks, reservoirs, or basins (*birkehs*) are associated with both episodic flow regimes and perennial flow. These are often connected with dams or bunds, the earliest of which, such as the Sadd el-Kafara in Egypt, date back to the middle of the third millennium BC (Fig. 1: location 13; Fahlbusch, 2004; Hodge, 2000a; Smith, 1971). Basins can be deep (>5 m) and therefore useful for storing water or much more shallow (<2 m) and therefore more suited to

the temporary holding of water at the head of a field system and to act as a flow regulator, where a deep tank would render some of the water unusable (Costa, 1983, p. 286).

Drainage

Unfortunately, as a means of getting rid of excess water, drainage systems have been less thoroughly investigated but are mainly known from Mesopotamian cities (Wilson, 2000a) rather than from the countryside beyond; if drainage canals existed, they are difficult to differentiate from water supply canals.

Earliest Forms of Water Supply

Wells were the earliest known constructed source of water in the Near East (Hodge, 2000b). The oldest examples were already recognizable by the Cypriot Pre-Pottery Neolithic B (Peltenburg et al., 2000) and the Pre-Pottery Neolithic C of the Carmel coast (ca. 7000–6200 BC) (Galili & Sharvit, 1998). The 7–8 m deep wells of Kissonerga-Mylouthkia in Cyprus (Fig. 1: location 14), dated to the period 8400–6400 BC, appear to have tapped small underground watercourses. They were equipped with hand- or foot-holds and were apparently used to supply water for sedentary dwellings (Peltenburg et al., 2000, pp. 846–848). These features appear to represent a fully formed well technology; therefore one can only assume that earlier examples of water holes have not yet been recognized.

Nearly contemporary with the early wells on Cyprus are barrages recorded in the desert south of Amman, Jordan. At Wadi Abu Tulayha (Fig. 1: location 15) and nearby sites (ca. 50 mm of rainfall per annum), several low stone walls have been found constructed across the wadi that are dated by association with a Late Pre-Pottery Neolithic B (late PPNB) agropastoral “outpost” settlement (Fujii, 2007). The barrages are interpreted as having been constructed to hold back water to provide essential moisture for crop cultivation or to supply additional drinking water for the nearby late PPNB community. Such early features are now supplemented by similar

water-gathering structures recorded from the desert margins in central Syria (rainfall 150–200 mm per annum). These PPNB features have again been recorded within “landscapes of survival” where subtle stone-built features are less likely to have been destroyed. The features consist of small water-gathering structures which enhance natural karstic hollows in the limestone but also include small basins (Geyer, Chambrade, & Coqueugniot, 2014). Consisting of small artificial “ponds” bounded by alignments of large stones presumably to gather runoff from the desert surface, the features are associated with abundant scatters of lithics, as well as later artifacts of the Bronze Age and Roman–Islamic date. Although not securely dated, these water-gathering structures and increasing numbers of similar features from the Syrian and Jordanian deserts (Geyer et al., 2014, note 18) together suggest that the development of water systems in the Middle Eastern deserts date back to at least 8000–7000 BC.

In parts of the Levant and Iran, early irrigation appears to have been associated with alluvial fans or minor rivers. Following the initial suggestion of Andrew Sherratt and the recognition of irrigation channels at Choga Mami (Fig. 1: location 16; Oates & Oates, 1976; Sherratt, 1980), early irrigation channels have been identified near Tepe Yahya in southeastern Iran (Fig. 1: location 17; Prickett, 1986) and on the Tehran plain near Tepe Pardis, the latter being dated by radiocarbon to ca. 5000 cal. BC (Fig. 1: location 18; Coningham et al., 2006, p. 51). These narrow, earth-lined channels buried below sites and within landscapes that are prone to burial by later sediments are difficult to find, but such locations provide a sealed stratigraphic context for channels; consequently the dates established (ca. 6000–5000 BC) appear relatively secure.

How the above developments relate to the earliest riverine irrigation systems of Mesopotamia is difficult to say, although evidence from excavations at Tell Oueli in southern Iraq suggests that early irrigation was already in place there by 6000–5500 BC (Fig. 1: location 19; Huot, 1996).

Irrigation in Southern Mesopotamia

Southern Mesopotamia, one of the early cradles of civilization and urbanization, was very much dependent upon the manipulation and management of water. The history, development, or practices of Mesopotamian irrigation have been summarized by Adams (1981); Pemberton, Postgate, and Smyth (1988); Postgate (1994, pp. 173–190); Charles (1988); Bagg (2012); Widell, Hritz, Ur, and Wilkinson (2013); and Tamburrino (2010). Evidence for the early history of water distribution in southern Mesopotamia derives from a range of sources: archaeology, paleobotany, ancient cuneiform texts (in Sumerian and Akkadian), as well as geomorphology and history, hence bringing together such a wide range of source materials can result in conclusions that may be difficult to harmonize. Effectively the history of water management in these alluvial lowlands picks up from that at Choga Mami, situated along the eastern fringes of the plain and can be continued at Oueli where a French team has documented the early history of irrigation during the Ubaid period.

During these earlier phases of the Holocene, settlement appears to have been associated with both rivers and marshes (Pournelle, 2007), but by about 4000 BC or slightly later, the distinctive patterns of settlement alignments recognized by Adams (1981) and Jacobsen (1960) started to appear along raised riverine levees.

Because the Mesopotamian plains exhibit very low gradients, the distribution of water laterally is difficult. However, the anastomosing (i.e., branching) river channels of the Tigris and Euphrates Rivers, being frequently raised upon levees some 1–5 m above the flood plain, offer the opportunity to distribute water down the levee slopes, which are significantly steeper than the longitudinal gradient of the plain (Adams, 1981; Fig. 6). This process appears to have resulted in a pattern of longitudinal channels and short (1–5 km) canals which must have contributed to the “herringbone” pattern of canals in many parts of the plain. In addition, longer canals were also constructed. For example, in his royal inscriptions, Ur-Nammu (ca. 2113 BC) claims to have

H

Hydraulic Systems in the Middle East, Fig. 6 Block diagram of levee in southern Mesopotamia showing the mode of downslope irrigation

authorized the excavation of major hydraulic works, and large canals, such as the 50 km-long Nina canal, were occasionally recorded (Rost, 2011, pp. 16–17). By the later second millennium BC, Adams (1981) recorded an increased number of longer cross-canals that linked earlier longitudinal channels.

One consequence of the limitations of the low-gradient landscape was that it was frequently difficult to raise water to the required level by gravity alone. Therefore artificial water-raising devices became increasingly necessary from the third millennium BC. Hence, we see evidence of *shadufs* (see below), and by the first millennium BC, a wider range of water-lifting devices were also in use, including the Archimedean screw (Dalley, 2013, pp. 32–34).

Although irrigation provided stable and higher yields, it also came at a cost, namely, salinization. Jacobsen and Adams have made a compelling case for the increased spread of salinization during the third millennium BC throughout southern Mesopotamia, eventually resulting in declining yields, a switch to salt-tolerant barley, and eventual settlement decline (Jacobsen & Adams, 1958). Although details of this salinization model have been disputed (Powell, 1985), salinization is clearly a perennial problem in the

region, and therefore any tendency to either violate fallow by cropping fields every year or extending cereal fields into low-lying flood basins (Altaweel, 2013) must have resulted in salinization and declining yields.

Mesopotamian systems were not, however, restricted to the broad plains south of Baghdad; they also extended further up the Euphrates. At Mari, administrative texts dating predominantly from the early second millennium BC testify to the existence of water-diversion features, canals, and different classes of irrigated and nonirrigated land (Fig. 1: location 23; Durand, 1990; Lafont, 2000, pp. 134–137). This textual evidence is supported by the presence of relict canals in the valley floor alongside the Euphrates which, although not well dated, appear to include major canals from the Bronze Age (Geyer & Monchambert, 2003).

Development of Water Supply During the Bronze Age in the Fertile Crescent and Levant

Outside the main irrigated lowlands, evidence for large-scale systems of water supply is limited, and hydraulic features appear mainly to have

been restricted to wells, pools, tunnels, and a few other examples of water capture.

In the southern Levant, bell- and bottle-shaped cisterns from sites at Mezar and Hazor provide evidence that the technology of storing water in such reservoirs was well advanced by the Chalcolithic and Bronze Age (Tsuk, 1997a, p. 13). For the southern Dead Sea region and the Levant overall, Frumkin (2002, p. 21) suggests that Bronze Age communities lacked sophisticated water supply systems and used water mainly from pools, cisterns, wells, and springs (Patrich & Amit, 2002, p. 9). The combination of springs, pools, reservoirs, and wells within the immediate limits of the settlement not only provided a convenient and accessible water supply for inhabitants, especially during times of siege, but they also may have served for watering flocks of sheep or draft animals. In a similar manner, the Bronze Age tunnels already mentioned at Kherabat al-Zeraqun in Jordan or at Troy in Turkey (Fig. 1: locations 8 and 9; Biernert, 2004; Latacz, 2004) would have ensured that the community inside the city walls was guaranteed access to water, even during times of conflict.

Overall, evidence of Bronze Age irrigation systems outside the Mesopotamian plains is limited. Examples include irrigation channels on the Beersheba plain in the northern Negev (Tsuk, 1997b, p. 130) and at Jawa, in northern Jordan (near Fig. 1: location 8; Helms, 1981). The latter site, dated to the Late Chalcolithic and EBI (late fourth millennium BC) and located in the arid Jordanian desert where rainfall is usually less than 100 mm p.a., was supplied by a sophisticated system of floodwater harvesting coupled with terraced gardens and pools (Müller-Neuhof, 2014). This system, which supplied sufficient water for a settlement of perhaps 5,000 people (Whitehead et al., 2008), is among the earliest known system of water harvesting in the Near East, other examples being known from Yemen (Harrower, 2008; Wilkinson, 1999).

A similar hydraulic landscape has recently been discovered within the zone of marginal rainfall at Al-Rawda in central Syria (Fig. 1: location 21). This system, dating from the third

millennium BC, comprised a series of embankments and transverse walls deployed to capture water into irrigated plots to support the inhabitants of this circular town (Castel & Peltenburg, 2007, pp. 4, 10). Overall, Jawa and Al-Rawda represent a phase of initial sedentary settlement of the arid margins of the rain-fed zone of the Levant at a time when the first cities were developing the northern Fertile Crescent. In southern Syria, water capture within cisterns and by wadi floor bunds and associated water channels supplied fourth and third millennium BC settlements with essential water for fields and domesticated animals (Braemer, Geyer, Castel, & Abdulkarim, 2010, pp. 103–107).

Although new discoveries, such as those around Al-Rawda, urge us to be aware that new data sources can transform our knowledge, it appears that agricultural production was predominantly a result of the following practices:

- (a) The use of rainfall as the dominant means of supplying water in areas where rainfall was greater than ca. 250 mm per annum.
- (b) The development of larger-scale irrigation systems in the alluvial plains of Mesopotamia and Iran.
- (c) The capture of small perennial flows, groundwater, runoff, and floods in the margins between the rain-fed zone and the true desert (Braemer et al., 2010).

The above water systems were all located close to or within the site itself, which implies that the technology of water supply was primarily deployed within a relatively short administrative reach of Bronze Age communities. In other words, the scale of the polities and the territorial boundaries of the settlements constrained the scale of water systems in use, a geographical limitation that was compounded by the needs of the communities to retain access to a reliable water supply during times of conflict or siege. After the Bronze Age, however, this was followed by a very rapid and extensive expansion of settlements and water management systems during the later territorial empires that have controlled the Middle East over the last 3,000 years.

Within Arabia, the development of oasis settlements at sites such as Hilli and Bāt in the United Arab Emirates and northern Oman (Fig. 1: locations 2 and 24) appears to have been associated with a combination of canal and well irrigation (Cleuziou & Tosi, 2007, pp. 154–155). Similarly, Yemen experienced the earliest phases of flood (*sayl*) irrigation within the Marib area (Brunner & Haefner, 1986), while in the Yemen highlands, runoff agriculture and valley floor check dams were in use (Wilkinson, 1999). Again, like their counterparts to the north, these were primarily small-scale hydraulic systems.

Water and Irrigation of the Later Empires

Although aggressive kings had created empires during the Early Bronze Age, only after the Bronze Age did political units increase in size to attain the massive scale and stability of the later territorial empires. At the same time there also appears to have been a shift in the scale of water management so that there was a significant reorganization of the settled landscape. These changes roughly coincided because, as has long been known, there is an apparent relationship between the scale and development of irrigation systems and the scale of the polities that administered them (Wittfogel, 1957). Nevertheless, as Adams has demonstrated, the really large-scale hydraulic systems seem to postdate the rise of centralized control and the early Mesopotamian empires (Adams, 1974; Marcus & Stanish, 2006, p. 4; Scarborough, 2003, pp. 17–19).

The significant changes in water supply and management that occurred during and after the Neo-Assyrian Empire (ca. 1200–612 BC) resulted in the following developments:

- An extension in the area of irrigated settlement, which included more dispersed, small settlements.
- Greater crop production in areas that were already capable of producing crops under normal rainfall (the limit of rain-fed agriculture being defined as 200–250 mm per year).

- The creation of water systems capable of supporting the growth of new and existing towns. This was especially the case for the Romanized Levant.

Many of the largest irrigation systems in the Middle East were constructed in southern Mesopotamia during the Sasanian (224–637 AD) and early Islamic periods (ca. 637–1100 AD) (Adams, 2006). However, major canals were also being built beyond the southern riverine zone, and water management technology spread into formerly more marginal Northern Mesopotamia by the authority of the kings of the larger empires.

To the west, in modern Syria, the Khabur Valley witnessed the construction of a major longitudinal canal system. This was initiated in the Middle Assyrian period around 1200 BC and then continued during the early first millennium BC coincident with the rapid growth of the Neo-Assyrian Empire (Ergenzinger, Frey, Kühne, & Kurschner, 1988; Morandi Bonacossi, 1996). It may also have continued in use into the Early Islamic period which demonstrates the durability of well-designed water supply systems.

Similarly, in northern Iraq, the Assyrian kings have left behind a remarkable record of canals which both increased agricultural production and also contributed to the pleasure of everyday life (at least for the king and his court) and provided water for religious purposes. Further north within Anatolia, some of the earliest examples of canal construction occurred in the eighth and seventh centuries BC, where Urartian engineers produced sophisticated canal systems to provide supplementary water to their settlements and fields (Fig. 1: location 28; Belli, 1999; Garbrecht, 1980).

Probably the most comprehensive Assyrian hydraulic engineering scheme was that of Sennacherib, who constructed four major canal systems in the hills and valleys to the north of Nineveh (Fig. 1: location 30; Jacobsen & Lloyd, 1935; Oates, 1968; Reade, 1978; Ur, 2005). According to the inscriptions, these were constructed in four stages between approximately 702 and 688 BC and were designed to irrigate

orchards and cereal fields and also served to keep the imperial gardens and parks around the city green (Bagg, 2000a, pp. 318–320; Ur, 2005). Inscriptions state that water was used to irrigate cereal fields, perhaps including sesame and flax fields, or orchards (Bagg, 2000a, pp. 317–318). There can therefore be little doubt that the canals did indeed play a significant role in the increase of agricultural production for the Neo-Assyrian state (Ur, 2005).

In terms of hydraulic technology, these canals were remarkable achievements. They incorporated elaborate offtakes and circumvented obstacles such as tributary valleys by means of sophisticated stone-built aqueducts, the best known being Sennacherib's aqueduct at Jerwan (Jacobsen & Lloyd, 1935). It was also around this time that water-lifting devices such as the *shaduf* became even more sophisticated and visible in the landscape, as illustrated in one of the reliefs in Sennacherib's Southwest Palace at Nineveh (Bagg, 2012, Fig. 14.2). The sophistication of the Assyrian water systems behind Nineveh and the ambiguity of ancient references to the Hanging Gardens of Babylon have led Stephanie Dalley to argue that the famous Hanging Gardens were, in fact, at Nineveh (near modern Mosul) rather than at Babylon in the southern alluvial plains. Overall, Dalley makes the case for the use of sophisticated water-raising devices such as the Archimedes screw in the seventh century BC (Dalley, 2013, pp. 33–34, 56–57, 205–207).

Shortly after the fall of the Assyrian empire, remarkably sophisticated hydraulic installations were constructed around the Achaemenid centers of Pasargadae and Persepolis in Iran. Of particular sophistication is the Achaemenid Dam of Sad-i Didegan and the perhaps linked structure of Sad-i Shahidabad which appear to have controlled and stabilized water from the Rud-i Pulvar River to irrigated agricultural areas downstream (De Schacht, De Dapper, Asadi, Ubelmann, & Boucharlat, 2012; Kleiss, 1988). The five dams recorded, ranging from 150 to 700 m in length, were of ashlar blocks and earthen fill construction, with well-constructed stone-built canals and a remarkable subdivided sluice structure (De Schacht et al., 2012, Fig. 7).

Hydraulic Systems in the Middle East, Fig. 7 The Balikh Valley in Syria showing the dense pattern of canals mapped from CORONA images and in the field. These represent a complex, tangled palimpsest of different cycles of use, reuse, and modification, mainly dating from the Hellenistic period and later (From Rayne, 2014)

Also near Pasargadae, in this case within the Royal Area of the site, Boucharlat (2009) has demonstrated that the Achaemenid gardens were actually much more extensive than the celebrated “Persian garden” described by Stronach (1978).

Like their Assyrian predecessors, the Achaemenid hydraulic works were not only of considerable sophistication, they were also harnessed to supply both functional needs and pleasure. They also demonstrate the sophistication of the engineers of the time, who were sufficiently sensitive to hydraulic challenges that they were capable of stabilizing uneven flows, incorporating sophisticated lifting devices and controlling flows in ways that became much more familiar in the classical world which followed.

Whereas Assyrian and Achaemenid water technologies were of considerable sophistication,

Hydraulic Systems in the Middle East, Fig. 8 Main features of the early Islamic city of Raqqa/Rafiq in northern Syria showing the course of an open channel which flowed through a tunnel to supply the Abbasid palaces

with water. To the east, a *qanat* originates in an area of elevated ground to the north of the civil settlement of Raqqa. Topography derived from ASTER GDEM (From Rayne, 2014)

later water supply systems were often densely distributed throughout the landscape. For example, within the Balikh Valley of Syria (Fig. 7), numerous irrigation systems dating to the Hellenistic and later periods demonstrate how some landscapes became almost dominated by canals and water works (Wilkinson & Rayne, 2010). Textual evidence in the form of letters from the site of Mari provides compelling evidence for water competition between Middle Bronze Age polities during the early second millennium BC. The dispute over water is clearly described in one of the Mari texts where downstream communities in the Balikh Valley complained that upstream users were depriving them of essential irrigation water (Dossin, 1974; Villard, 1987). However, the first archaeological evidence of major canal systems appears somewhat later,

but by the Hellenistic through early Islamic periods, major canals existed along much of the length of the Balikh River Valley (Rayne, 2014). Their dimensions and the size of the areas served by patterns of canals and offtakes suggest that they must have significantly reduced the overall flow of the river (Wilkinson, 1998; Wilkinson & Rayne, 2010). Downstream, additional water management remains are concentrated around Raqqa (Rayne, 2014; Wilkinson & Rayne, 2010). During the Abbasid period, when Raqqa was briefly a capital city under the caliph Hārūn al-Rashīd, the city was supplied with water from a *qanat* which led into several open channels, and there was a separate water supply which served a large palace complex north of Raqqa (Fig. 8). Upstream, the large-scale irrigation systems discussed above generated crops which may

have supported Raqqa with food as well as providing a resource for taxation.

In both the Balikh (around Hisn Maslama) and Euphrates Valley near Balis (Fig. 1: location 25), the field evidence of early Islamic canals can be linked to a specific individual, namely, the Umayyad prince Maslama (a son of Abd al-Malik), who made considerable investments in agricultural activities in the early eighth century AD and who claims to have dug canals in both locations (Ashtor, 1976, p. 62; Le Strange, 1905, p. 105). Extensive canal systems have also been recorded downstream of Deir el-Zor. Dating to the period of the Islamic caliphates, these are inferred to have formed part of the agricultural supply network of the capital cities of Baghdad and Samarra (Berthier et al., 2001; Kennedy, 2011).

Elsewhere, the development of the qanat resulted in a dramatic transformation of the landscape. Qanats (*falajes* or *aflaj* in Oman) utilize areas of enhanced groundwater and flow day and night. They require both sophisticated allocation systems to optimize the use of water and considerable financial investment for their construction and maintenance. Not only did they result in the massive spread of “qanat settlements” across the landscape but at a smaller scale, they have also structured the development of the social landscape.

Qanats are considered to have spread during the early first millennium BC, usually having developed first in Iran or neighboring Anatolia. However, recent excavations of underground channels and associated settlements have convincingly extended this initial area to include southeastern Arabia. It has also been suggested that the qanat logically developed out of the excavation of tunnels for urban water supply, perhaps as early as the Bronze Age tunnels at Kherabat al-Zeraqun in Jordan or at Troy in Turkey (Fig. 1: locations 8 and 9; Biernert, 2004; Latacz, 2004). Alternatively, techniques of tunneling for water may be a by-product of mining technology (English, 1998, p. 188; Forbes, 1964, p. 157).

The most recent evidence now suggests that qanats were supplying water for Iron Age II

settlements in southeastern Arabia as early as 1000 BC (near Fig. 1: location 2; Boucharlat, 2001; Magee, 2005, p. 222; al-Tikriti, 2002). This challenges the earlier notion that qanats were invented in northwestern Iran or northeastern Turkey and then dispersed through Iran and into Arabia, in part under the administrative umbrella of the Achaemenids (Laessøe, 1951; Wilkinson, 1977). By the Roman–Byzantine and Partho–Sasanian periods, they had become common throughout the Near East. For example, Lightfoot asserts that of a sample of 67 “qanat Romani” from throughout Syria, some 90 % were associated with Roman–Byzantine sites, which consisted of small towns, “outpost,” or “guard-house” ruins (Lightfoot, 1996, p. 325). Also in Syria, networks of relict qanats have been recorded using remote sensing south of the Sajur River in Syria near Membij (Dan Lawrence & Niko Galiatsatos pers. comm.), and based on historical sources, these have been interpreted as Hellenistic (Lightfoot, 2003). In this area on the margins of the rain-fed cultivation, although qanats were apparently employed for irrigation, at least some must have fed water to the shrines and temples within the Hellenistic–Roman city of Hierapolis (modern Membij).

The case can therefore be made that the extension of settlement during the first millennium BC and AD was partly the result of the development or introduction of new water supply systems. This extension of irrigated settlement occurred in both the moister area of rain-fed cultivation and in adjoining desert areas, and in the latter region, this entailed the resettlement of the steppe at sites such as Resafa during the Late Antique period (Beckers, Berking, & Schütt, 2012; Geyer, 2001).

The water technologies of the later empires also enabled crop production to be intensified. This took the form of small plastered open channels which can be recognized widely throughout northern Syria as belonging to the Hellenistic to Islamic periods. Near Carchemish, for example, small plastered channels led water from water sources in the hills to small settlements in the nearby Euphrates Valley (Fig. 1: location 31; Wilkinson, Peltenburg, McCarthy, Wilkinson, & Brown, 2007, 236–38).

The combined extensification of settlement and intensification of agriculture during the Roman–Byzantine periods was carefully configured to the prevailing hydrological conditions. Hence, in the semi-arid fringes of the Hauran Mountains in southern Syria, a significant spread of settlement was associated with Roman flood-water farming, canals, and qanats, in some cases employing a technology that resembles the traditional water-gathering technologies of the Nabataeans and other Arabian communities (Braemer et al., 2010).

During the later empires, water use also became diversified so that by the first millennium BC, water systems were being used for far more than irrigation and domestic consumption. By the first millennium AD, water was harnessed for power, in the form of water mills (Fig. 9), to supply new and growing towns, as in the proliferating aqueduct systems of the Levant (Amit et al., 2002), and for novel functions such as industrial-scale brick-making in frontier areas. Also by this time, a range of hydraulic devices were being introduced and adopted to make water supply more efficient and effective (Amit et al., 2002; Hodge, 1991). These included innovations such as the incorporation of siphons into canals and conduits, which enabled water to be led below rivers or valleys to continue flowing at almost the same elevation. By the Roman period, aqueducts were an intrinsic feature of early towns. However, as Brent Shaw has cautioned, aqueducts did not create the conditions for the existence of towns but rather they were the “end product, the result of prolonged economic development within the empire which led to more intense local economic networks, denser nucleated populations, and, above all, wealthy local elites” (Shaw, 1991, p. 68).

Urban aqueducts usually drew their water supply from springs or riverine pools, the flow of which was sometimes held back by bunds or “spring houses” that regulated flow (Patrich & Amit, 2002, pp. 10–11). Channels were usually cemented with hydraulic plaster and were of modest scale because both their discharge and flow variations were less than those of major rivers. Topographic discontinuities were

Hydraulic Systems in the Middle East, Fig. 9 Islamic water mill at Jam, near Siraf, Iran. The penstock is the circular masonry structure in the mid-ground and the milling chamber is below

circumvented by the construction of aqueduct bridges or inverted siphons and occasionally sealed fired clay or stone pipes that made it possible to traverse large valleys (Peleg, 1991). The similarity of open channels throughout the Middle East testifies to a certain common practice, with the Islamic systems building upon Roman and Sasanian predecessors, and these in turn enhanced earlier Assyrian and Urartian systems. In addition, however, innovations were introduced from the classical world (Kamash, 2006, 2012); therefore the water systems of the Hellenistic period and later represent an amalgam of indigenous and classical technologies.

During the later empires, water distribution engineering also became more adventurous (see essays in Wikander [ed.], 2000) and greater use was made of novel or ancient water technologies

to lift water via the simple bucket, the *shaduf*, and a range of water wheels (Oleson, 2000). These developments were not all inventions of the Greeks and Romans, however; the first illustration of the *shaduf* is known from a Mesopotamian seal dated to ca. 2400–2200 BC (Bagg, 2001, pp. 40–41; Drower, 1956; Oleson, 2000, p. 227), whereas the pulley is known from Assyrian reliefs as early as the ninth century BC. Water was also used to generate power using water mills whose penstocks for raising the pressure head became conspicuous features of the landscape (Fig. 9) from the Roman–Parthian period onwards (Wikander, 2000). These were not simply employed for milling cereals from the neighboring fields; they were also used for industrial purposes such as fulling – that is, scouring and thickening cloth, especially wool – and perhaps grinding minerals prior to smelting. By the early years of the first millennium AD, water had become a common feature of industrial processes and was being used for basic sustenance and agriculture (Wilson, 2000b; Wikander, 2000).

Some of the more interesting applications of water technology came during the early centuries of the Islamic period. In addition to using conduit and canal systems to provide towns and fields with a clean and reliable water supply, communities also captured runoff and flood waters to supply the resting places along trans-Arabian pilgrim routes (al-Rashid, 1980). This major engineering enterprise provided cisterns and wells along the entire length of the pilgrim routes from Basra and Najaf (in Iraq), the Levantine cities and Yemen, and across the desert toward Mecca (Fig. 1: location 34; Fig. 7a, b) (Wilkinson, 2003, pp. 165–168).

The Sasanians (224–651 AD) took the construction of large-scale water systems to its peak with, for example, the realization of the spectacular 150 km-long Nahrawan canal in Iraq (Adams, 1965); the canals, water mills, and dams at Shushtar; as well as the water mills of the Deh Luran plain in Iran (Christensen, 1993; Neely, 2011). Similarly, the water systems associated with the Gorgan Wall in NE Iran demonstrate how Sasanian engineers initiated a network of canals along the desert fringes which then

supplied water apparently for the construction of the frontier wall itself, for brick making and supplying the forts along the wall (Sauer et al., 2013).

Water Management, Investment, and Decline

Water was also regarded as a sacred medium, and the conveyance of water endowed status upon the individuals who built or invested in waterworks. The Assyrian kings were quick to acknowledge their debt to the gods for water and the importance of making appropriate offerings to them. A sustained and pure water supply was crucial for many religious buildings right through to the mosques of the Islamic period.

For the Middle East, one can now sketch a continuous history for the development of water systems from the earliest wells of the Neolithic, through PPNB water-gathering systems of the Jordanian and Syrian deserts, to the later Neolithic channels of Iran and the Iraqi borderlands through until the first recognition of irrigation in southern Mesopotamia at the site of Oueili. From that point, we then have a continuous record of irrigation systems, particularly in Mesopotamia, but also in parts of Syria, the Jordanian desert (Jawa), and the Negev. By the fourth millennium BC, early water management systems are also recognized in Yemen (Fig. 10) where they must have formed the foundations of the dramatic irrigation systems at Marib and in the Hadhramout (Brunner & Haefner, 1986; Charbonnier, 2011, pp. 145–146). By around 1200 BC, major water management systems then spread into the rain-fed farming zones of the northern Fertile Crescent, as well as into the Yemen highlands, and in both regions, they contributed to the intensification of farming and the raising of tax revenues.

The range of technological innovations that occurred during the first centuries BC and AD is remarkable and testifies to the propensity for technologies to be transferred under the later empires, either within the empires (by forced transfers of populations from place to place) or between them as in the famous capture of the

H

Hydraulic Systems in the Middle East,
Fig. 10 Valley-floor terrace/check dam buried by deep
sequence of sediments accumulated behind the Himyarite

dam of Sedd Ádhra'ah II in Yemen (ca. first century AD).
Soil accumulated behind the check dam yielded a radio-
carbon date of 4960 ± 80 BP (cal. BC 3955–3630)

Roman army in 244 AD by Shapur, in the battle of Carrae /Harran. This resulted in the acquisition, by the Persians, of an abundant supply of captive Roman labor, as well as much expertise in hydraulic technology (Howard-Johnston, 1995, pp. 161, 181). The transfer of skills from one industry to another was also a significant factor in accelerating hydraulic progress.

Just as greater investment resulted in the growth of water supply systems, the lack of investment resulted in decline. Not only were massive resources (both labor and financial) required for the construction of large-scale regional water supply systems, their maintenance depended on a continued high level of commitment and investment. This was especially the case because the large-scale systems often introduced many new problems, such as the need to negotiate rights to preexisting water supply channels and to counteract the effects of salinization.

In both the riverine zone of Mesopotamia and the non-riverine zones, it is thought that hydraulic

developments went into a decline after the tenth century AD and especially so between the thirteenth and fifteenth centuries AD (Christensen, 1998). Decline has been variously ascribed to a range of factors: lack of investment during the ninth and tenth centuries AD by the Abbasid caliphs, destruction by the Mongols (in the thirteenth century AD) or Tamerlane (fourteenth century), salinization (in southern Mesopotamia), vulnerability to flooding (the Nahrawan canal in the Diyala region and the Marib Dam in Yemen), warfare (Christensen, 1998; Lapidus, 1988, p. 136), as well as other causes.

This decline in Iran and Iraq was also evident elsewhere in the Middle East. For example, in the northern Negev Desert, areas that had become agricultural during the Roman/Nabatean and Byzantine periods then went into a precipitous decline in the tenth and eleventh centuries CE (Rosen, 2000).

Nevertheless, despite these declines, in the sixteenth and seventeenth centuries CE, Ottoman

tax records indicate that in the Khabur and Balikh Valleys of Syria, canal irrigation continued to be used (Hütteroth, 1990), and along the Euphrates and in the northern Levant, there are examples of many systems that have survived until modern times.

Hydraulic Technology in Egypt

Claire Cookson-Hills

Queen's University, Kingston, ON, Canada

Neolithic hydraulic technology in Egypt developed alongside agriculture, when Egyptians began to alter the river's regularly flooded banks to grow more crops more easily along the Nile (c. 5700–c. 2800 BCE). Since the Nile Valley floods once every year, rising in April and receding in July/August, the flooded areas of the Nile Valley were an excellent place to settle and grow crops. The earliest hydraulic technology was utilized to collect those floodwaters and move them between agricultural plots using diversion technologies. The river also serves as a giant communication and transportation canal, as the current flows north, but the winds blow southwards. The river, therefore, naturally facilitates movement of people, ideas, and goods between the river's delta at the Mediterranean Sea and the first cataract at Aswan and aids political unification (McNeill, 2000, p. 166). Although land-based technologies were popular at various points in Egyptian history, such as roads under the Romans or railways under the British, the Nile has acted simultaneously as highway, irrigation canal, and telegraph network for millennia. The earliest archaeological evidence of hydraulic technologies is Predynastic: by 3100 BCE a system of artificial basin irrigation diverted streams and floodwaters, raised levees to control the floodwater, built small earthen dams, and modified natural overflow channels into drainage canals in order to move the river's floodwaters wherever they were needed.

By the time that Egypt was politically united under the Old Kingdom, some of the hallmarks of Egyptian hydraulic technology had been invented or transferred from nearby civilizations. Nilometers to measure the height of the flood date back to around 3000 BCE. The most famous Nilometer at Rhoda Island was installed in

622 CE. The first large-scale dam was constructed in Lower Egypt near Helwan around 2650 BCE, the Sadd el-Kafara. The largest dam in the world at the time, this structure was intended to control the Nile's floods and would have stored 0.5 million cubic meters. However, it was destroyed by a flood shortly before its completion (Mays, 2008; Fahlbusch, 2009, p. 15). Fahlbusch concludes that the engineering knowledge needed to build the Sadd el-Kafara implies that other smaller-scale dams were constructed in Egypt and the Middle East, but these have been erased from the historical and archaeological record. However, small-scale technologies also flourished. At the level of the individual farm, the *shaduf*, a manual system of raising water from the Nile, was developed around 2000 BCE (Butzer 1976, 47). The *shaduf* is still used in Egypt today and represented one of the major inventions for drawing water onto the fields when the water was low. The *shaduf* is a bucket and rope attached by a pole to a counterweight. The counterweight lowers the bucket into the river and draws the filled bucket back up without the person having to fight against gravity. With the *shaduf*, Egyptians could grow at least two crops per year – one in the immediate recession of the Nile's water after the flood and another in the winter when the river was low.

Other large-scale hydraulic technologies were part of extending irrigation networks. One was the construction of the reservoir called Lake Moeris in the region of the Faiyum. By 2300 BCE an existing canal was transformed into a large-scale construction project connecting the Nile with the Faiyum, a low-lying depression to the west of the river. The reservoir that this canal and its diverted floodwater created was large enough to control high floods, regulate water in the winter, and irrigate the surrounding area. It was utilized as a reservoir from 2300 BCE to 23 BCE when the nearest branch of the river dried up (Chanson, 2004). The first hydraulic project in the Suez region was an irrigation canal constructed around 1850 BCE, extended by the Ptolemies as far as the Bitter Lakes, and

kept open until the Roman era. That canal was filled in for military purposes by the Abbasid caliphs in 775 CE (Encyclopedia Britannica). Four thousand years ago, ancient Egyptians used hydraulic technology to plant and irrigate two crops per year, measure the flood, and successfully control flood levels and attempted flood control in the Nile Valley.

During the Ptolemaic period, the *saqiya* and Archimedes screw were introduced into Egypt. Residents of Alexandria were at the forefront of Hellenistic science, contributing to hydrostatics and invention (Mays, 2010, pp. 15–16). The *saqiya*, probably introduced from Persia, is a waterwheel made of a circle of buckets wherein each bucket draws water up directly from the river or a canal when at the bottom of the circle. It is poured out when the bucket gets to the top; the water then flows into a canal to be drawn onto the fields (Ritner, 1998, p. 2). In order to turn the wheel of buckets, which require a consistent amount of energy, *saqiyas* in Egypt were usually oxen-drawn. Archimedes screws are a screw inside of a hollow pipe, which draws water upwards; Archimedes screws in Egypt were mostly pumped by hand. These devices improved upon but did not entirely displace the *shaduf* for farm-based hydraulic technology. Instead, when paired with irrigation canals to move the water, the *saqiya* and Archimedes screw meant that a system of year-round irrigation could be implemented; farmers could now grow crops perennially because the canals brought the water and these technologies lifted the water onto the fields (Butzer, 1976).

In contrast to other parts of the ancient Middle East and Africa, ancient Egyptians were not highly invested in utilizing groundwater reserves, although there was some use of well water. In the Nile Valley and the Delta, wells, qanats, and groundwater usage was supplementary to rather than substitutive of riparian irrigation because of the regularity of the Nile's rhythms and the potability and abundance of its water (Shahin, 1991, p. 7). However, away from the Nile, wells were sunk as early as the 4th Dynasty (c. 2613–2494

BCE). These ancient wells were sunk up to 100 m deep through soft rock such as sandstone or limestone. In the western desert, oasis wells have been dated to as early as 905 BCE (Shahin, 1991, p. 5). Qanats were introduced to Egypt when the Persians invaded in the fifth century BCE. These underground aquifers collected groundwater. Like the wells, they were used mostly in oases in the western desert; the qanats at El-Kharga Oasis have been extensively studied (Wuttman, Gonon, & Thiers 2000). During the Roman era, underground water-collecting galleries were used along the Mediterranean coast.

In the early Islamic era (641–1171 CE), hydraulic technologies from across Afro-Eurasia became incorporated into Egyptian agriculture as the best methods to cultivate a new series of crops, including sugar, cotton, rice, and sorghum (Bowman & Rogan, 1999, p. 2; Burke, 2009). However, Egypt not only imported hydraulic technologies, it exported them as well. Especially under the political (the Islamic dynasties) and linguistic (the Arabic language) unification, Egyptian technologies, such as the *shaduf* and *saqiya*, were incorporated into a “water management technological package” that was diffused across the Islamic world (Burke, 2009, p. 174). After Egypt came under Ottoman control in 1517, extant Egyptian hydraulic technology was used to make Egypt the Ottoman granary. Special emphasis was placed on perennially irrigating the crops using deep irrigation canals; these canals needed annual clearing (Mikhail, 2011).

In the nineteenth century, large-scale hydraulic technologies took pride of place. Under autonomous Ottoman governor Sa'id Pasha, the French engineer Ferdinand De Lesseps designed and constructed the Suez Canal. This transportation canal, built between 1859 and 1869, was 164 km long and 8 m deep. When completed, it connected the Mediterranean and Red Seas and obviated the need to sail around the Cape of Good Hope. Constructed mostly with French money and Egyptian forced labor, the Suez Canal has since been widened, deepened, and lengthened, but its importance as a sociopolitical, communication,

and transportation hub has continued. Egypt's nationalization of the canal in 1956 caused the Suez Crisis. In addition, the Suez Canal Company completed the Sweet Water Canal in 1863 to send drinking water from the delta to Suez. Other transportation and sanitation canals were constructed during this time, including the Mahmudiyya Canal, which connected the Nile to Alexandria and brought freshwater to the delta (Tignor, 2010, p. 215).

In order to grow better summer crops, especially long-staple cotton, nineteenth-century Ottoman governors instituted a series of hydraulic technologies. They increased the number of deep canals and constructed the Delta Barrage north of Cairo. Originally finished in 1862, the barrage was supposed to raise the summer water level in the Nile delta, but was structurally defective and had to be abandoned. During the 1880s, the delta Barrage was repaired by the British during their occupation of Egypt (1882–1914). The British constructed other large-scale irrigation technologies to increase the amount of water available for summer crops. The most important of these technologies was the original Aswan Dam (1902, heightened in 1912 and 1933). The Aswan Dam created a reservoir in the valley of the Nile, regulated the river's water against high or low floods, expanded perennial irrigation southwards into Middle Egypt, and began large-scale desert reclamation programs. After 1933, the Aswan Dam was also used to generate hydroelectric power. The British also built irrigation canals and a series of barrages along the Egyptian Nile to raise the water levels and carry this higher water to the places where it was needed (Cookson-Hills, 2013).

Egypt lost its vulnerability to, and natural resources from, the Nile floods in 1963, when the Aswan High Dam turned the Egyptian Nile into a vast network of canals. This hydroelectric megaproject stores 162 billion m³ of water and generates 2.1 gigawatts of electricity, and the reservoir, Lake Nasser, stretches 550 km behind the Aswan High Dam into the Sudan. The Egyptian Nile's entire volume is measured,

distributed, and regulated throughout northern Egypt and the delta, and Egypt is no longer dependent on the uncertain flooding of the river, with its potentially high or low floods. Since their connection to the river via a drainage canal in the 1970s, the Faiyum and Lake Moeris are once again used to regulate irrigation projects (El-Shabrawy & Dumont, 2009).

However, the total regulation of the Egyptian Nile has had difficulty providing water to Egypt's burgeoning population, which reached 82.5 million in 2011. Since the construction of the Aswan High Dam, much of the traditionally agricultural land in the Egyptian Delta has been brought under urban development. However, the total amount of agricultural land has increased from six in 1972 to eight million acres in 2003. Large-scale government reclamation projects under Nasser, Sadat, and Mubarak (most recently the New Valley Project which opened in 2005) have been responsible for this increase in acreage while being roundly critiqued (Sowers, 2011). Modern Egyptian hydraulic technology, like that in the Islamic world, has been borrowed from around the globe and shaped global projects, with a tendency towards large-scale government projects – dams, canals, reclamation projects, etc. At the same time, the Nile is being heavily recycled in water treatment plants – each drop was recycled up to three times as of 2009 (Dumont, 2009, p. 18). Egyptian hydraulic technology has been making increasing use of its groundwater resources in an attempt to make up the difference between an expanding population and fully utilized freshwater resources from the Nile (Tahlawi, 2008).

Hydrologic Engineering of the Tiwanaku

Charles R. Ortloff^{1,2} and John W. Janusek³

¹CFD Consultants International, Los Gatos, CA, USA

²Research Associate, Department of Anthropology, University of Chicago, Chicago, IL, USA

³Vanderbilt University, Nashville, TN, USA

The city of Tiwanaku, located at the southern edge of the Lake Titicaca Basin at an altitude of 3,800–3,900 m, has been the subject of archaeological research since the late nineteenth century. Excavations revealed extensive monumental complexes and residential districts (Janusek, 2004; Kolata, 2003; Ponce Sanginés, 1961, 1972; Vranich, 2009), indicating the urban core covered an area of 4–6.5 ha. While previous research demonstrated Tiwanaku agricultural hydrological technology (Kolata and Ortloff, 1996; Ortloff, 1996, 2009), aspects of this technology applied to the city’s urban water systems were not investigated.

A massive ditch surrounds Tiwanaku’s northwest monumental complex. Several researchers have characterized this feature as a water-retaining, defensive moat that separated Tiwanaku’s central monumental complexes and elite residences from surrounding urban peripheries (Kolata, 1993; Posnansky, 1945). Drawing on data that incorporates ground survey, newly discovered aerial photographs, and Google Earth imagery, the moat, renamed the “perimeter canal,” served several purposes as a hydrological regulator, controlling aquifer drainage and surface runoff to limit rainy season flooding while promoting rapid soil dry-out after the end of the rainy season. The present reporting of the perimeter canal’s hydrological function demonstrates that water management interwove practical and ritual roles for the city of Tiwanaku.

Hydrologic Engineering of the Tiwanaku,
Fig. 1 Schematic drawings of the “moat”: (a) Posnansky’s final rendering of the “moat” in 1945 (Plate

III); (b) Bennett’s (1931) “simplified” rendering of the “moat” based on Posnansky’s surveys conducted in 1904 and 1912

Perimeter Canal Archaeological Perspectives

Archaeological perspectives on the perimeter canal’s purpose began with Posnansky’s (1945, II,

pp. 121–112) conclusion that a continuous, water-filled moat surrounded Tiwanaku’s urban core (Fig. 1b) with defense as its main purpose. Kolata (1993) stated the moat distinguished the monumental core from urban peripheries, creating a

H

Hydrologic Engineering of the Tiwanaku, Fig. 2 Composite image from the Sawyer aerial photos noting key hydrological features in the northern portion of

the perimeter canal area showing drainage into the C' floodplain and the C canal leading perimeter canal water to the Tiwanaku River north of the monumental core

“concentric hierarchy” that punctuated the elite status of ceremonial core residents. Several investigators (Denevan, 2001; Browman, 1978, 1997) concurred that a moat-like structure surrounded Tiwanaku’s core while other researchers (Bentley, 2013, p. 122; Isbell, 2013, pp. 178–180) disagreed on its extent. Photographs taken in the late nineteenth century by Uhle and Bandelier together with Bennett’s ground drawings (1931) (Fig. 1a) fail to show evidence for a channel where the canal’s south arm would have passed. To resolve these contentious views, newly discovered aerial photographs indicate that a north–south-oriented canal intersected with the perimeter canal’s south arm, but these features became obscured through runoff-induced, erosion/deposition events over the 1,000-year hiatus since the site was abandoned.

The data assemblages deployed in hydrological analysis include survey, mapping, and excavation (Couture and Sampeck, 2003; Janusek & Earnest, 1990; Kolata, 2003), Google Earth imagery, and the 1930s high-resolution aerial photos over the site of Tiwanaku. The photos (Figs. 2 and 3) reveal the site during the rainy season, providing an aerial view of Tiwanaku’s water-retention features. Later research involved survey and mapping of hydrological features within and immediately surrounding the site, using the aerial photos to verify discovery of remnant portions of the perimeter canal. The canal’s east arm averages 5–6 m deep and ranges 18–28 m in top width; the west arm is not apparent as contemporary structures cover the area. Posnansky suggested that much of the canal had

Hydrologic Engineering of the Tiwanaku,

Fig. 3 The Mollo Kontu canal (M) as depicted in the (a) Sawyer aerial photos and (b) recent Google Earth satellite imagery

been filled by erosion “detritus” (1945, II, p. 121), yet ground survey, aerial photos, and Google Earth imagery indicate that a north–south canal passed through the Mollo Kontu sector of Tiwanaku and terminated precisely where the south canal arm would have passed (path A–B in Figs. 2, 3, and 6) and was geometrically similar to the east and west perimeter canal arms. Figure 4 shows this canal connection added to the entirety of the perimeter canal (Kolata, 2003, p. 178). Multiple subterranean drainage canals originated in the area of the Mollo Kontu canal intersection with the south canal arm. One such canal was located under the Putuni complex to the north of

the intersection junction (Figs. 5 and 6) and directed water at a 2° grade from the subterranean inlet toward the Tiwanaku River north of the site (Couture and Sampeck, 2003; Janusek, 2004; Kolata, 1993). A fraction of accumulated water in the south canal arm flowed into the subterranean canal inlet to provide flushing water to remove waste material from the Putuni complex; the remainder of the south arm water flowed laterally into the east and west perimeter canal arms then downhill into the north arm where water was conducted to the Tiwanaku River. The north arm of the perimeter canal was interlaced with agropastoral features on the northward

plain that drops sharply downward several meters toward the Tiwanaku River’s marshy floodplain. One portion of the perimeter canal’s east arm turns westward and disappears into the marsh

(Fig. 2) with an imbedded canal that continues northward toward the river. At the west end of the northern arm, one portion of the arm turns sharply to the east and disappears into the marsh north of

Hydrologic Engineering of the Tiwanaku,

Fig. 6 FLOW-3D CFD model of the hydrological and architectural features of the Tiwanaku urban core identified by letters. Model is a best-estimate representation of the original tenth century CE site layout from the aerial photo source and ground survey

the Kalasasaya while an ancillary canal arm continues northeast toward the river. Thus, the north arm of the perimeter canal originated branch canals that drained east and west perimeter canal arms and marshy floodplain groundwater to the Tiwanaku River. Survey and aerial photography show extensive raised-field systems in the marsh area indicating a productive agricultural area for the expanding urban center.

The Perimeter Canal in Tiwanaku's Urban Hydrological Network

The concentration of water features shown in aerial imagery associated with the ceremonial core region and adjacent urban structures suggests that the perimeter canal served an integral role in an intricate urban hydrological network. Beyond seasonal rainfall, an additional city water resource consisted of a deep groundwater aquifer that originated from the foothills of the mountainous Corocoro formation (Posnansky, 1945, II, pp. 118–119) and drained into Lake Titicaca. This aquifer was supplied by infiltrated rainfall over many centuries from vast watershed areas to the east and south of the city. Several landscape features in the southern portion of Tiwanaku were engineered to utilize this subterranean water

resource. The westernmost was Choquepacha (Bruno, 1999; Janusek, 2008; Kolata, 1993), a natural spring on a bluff southwest of Pumapunku that was fitted with canal stones carved to convey water to surface canals directed toward the city center (Posnansky, 1945, II: Fig. 42). Combined with the adjacent Challa Jawira stream that drained a marshy area of the terreplein and opened up pastoral-grazing lands on the west edge of Tiwanaku (Bruno, 1999), channeled water from this stream and adjacent springs provided water to multiple northward-flowing canals supplying water to multiple *qocha* regions (Fig. 2), canals east of the perimeter canal, and the Mollo Kontu canal. Several prominent water resource features relate to the hydrological function of the perimeter canal. The first is the Mollo Kontu A-B canal that conducted water from the southwest portion of the site near the Pumapunku complex (Figs. 2, 3, 4, and 6) into the south arm of the perimeter canal. A second feature is a cluster of sunken basins (*qochas*) that occupied the southeast portion of the site (Fig. 2). Qochas are pits excavated into the deep groundwater capillary zone to provide moisture for planting surfaces while creating micro-lacustrine environments that attract waterfowl (Craig, Aldenderfer, Rigsby, Baker, and Blanco, 2011; Denevan, 2001). The aerial photos depict a series of canals

dendritically linking individual qochas to each other and ultimately linking into a large northward-flowing channel (Figs. 2 and 4) – the Akapana East channel – that drained into the east arm of the perimeter canal. Here individual qochas were linked by sequential downslope canals so that water exceeding a given height in a qocha is passed on to the next downslope qocha; this limited water height in individual qochas consistent with their agricultural function. While the qocha system functioned well during the rainy season, during the dry season agricultural activity was sustained from channeled Corocoro spring flow to supplement the capillary fringe of the deep groundwater layer in qocha bottommost regions. A further water feature was a long outer channel that bounded the east side of Tiwanaku (Fig. 2).

While the role of this channel is unclear, its southern portion follows an alignment that mirrors that of the Pumapunku complex to the west while its northern portion bounds the east edge of the site with north-direction orientation. The Akapana East canal links through a connector canal to the north arm of the perimeter canal indicating that the outer channel was part of the broader urban hydraulic network. The areas east of this channel contain Tiwanaku's residential sectors and include Ch'iji Jawira, a barrio of ceramic producers that depended on a constant water supply (Janusek, 1999; Rivera Casanovas, 1994, 2004). Immediately east of this sector is a brackish marsh. Fed by rainwater and Corocoro's aquifer, this outer channel provided fresh water for Tiwanaku's easternmost residential sectors. As noted, the northern portion of the perimeter canal branched into a marshy floodplain area (Fig. 2 and 6-C') between the river and the alluvial plain that Tiwanaku occupies and served to drain surface runoff and groundwater north of ceremonial/residential areas into the Tiwanaku River.

Intricate surface and subterranean canal networks provided effective drainage within the area bounded by the perimeter canal. The elaboration of these networks indicate they were built to draw attention to water moving through intricate surface and subsurface constructions that drained the

interior floor of the Sunken Temple and areas outside the Kalasasaya platform (Ponce Sanginés, 1961, 1972). Constructed later, the multi-tiered Akapana pyramid monument incorporated an elaborately constructed, serpentine stone-lined canal network that routed water away from the uppermost down through successively lower platforms to discharge through portals in its basal terrace (Kolata, 1993, 2003). Water then flowed through surface channels at the base of the Akapana into the perimeter canal that carried water into subterranean canals to the east and west of the structure (Bennett, 1934, pp. 378–385). Water was temporarily pooled in sections of ceremonial center sunken courtyards, rendering them iconic “lakes” for ritual events.

Excavations between the Putuni and Kerikala complexes provided a sense of how structures within the ceremonial core articulated with Tiwanaku's subterranean drainage infrastructure (Couture and Sampeck, 2003; Janusek, 2004, p. 146). This area housed high-status groups until at ~800 CE the construction of the Putuni platform repurposed the space to support ceremonies (Couture and Sampeck, 2003; Janusek, 2004; Kolata, 1993, 2003). Reconstruction required new canal networks interlaced into the older system. Each sequential structural ensemble maintained architecturally aligned secondary canals fed by smaller tertiary canals. Most surface canals fed into subterranean canals consisting of sandstone slabs standing approximately one meter high and 0.8–0.9 m across (Fig. 5) that carried water northward on a 2° grade. An early French expedition to Tiwanaku identified one of these primary canals ~3.5 m below the ground surface (Créqui-Montfort, 1906) with later investigators (Couture and Sampeck, 2003; Janusek & Earnest, 1990; Ponce Sanginés, 1961) adding further details on the construction of the canal. An additional reason for the subterranean Putuni canal was to support drainage from a series of upper-level canals located in the monumental core. Only some of the most important secondary canals fed into the subterranean canal, such as the east–west-tending East Palace masonry canal that followed predominant architectural

orientations. The Putuni subterranean canal primarily carried sewage drainage northward and downslope toward the Tiwanaku River. In the 1930s, Bennett located a secondary subterranean canal 1.7–2 m below the surface that carried water directly west from the Akapana and toward a deeper, southward-bound primary “Akapana East” subterranean canal that drained into the “Akapana West” canal. Finally, at least one canal near the Kerikala structure to the northeast flows on a downward gradient to the west, suggesting that it may have fed into yet another primary canal located under that structure.

Encircling Tiwanaku’s monumental complex, the perimeter canal constituted a hydraulic circuit that articulated with all these hydrological features (Figs. 4 and 6). An overview of hydraulic features indicates that water was transferred from multiple Corocoro spring sources into several canals adjacent to and connected into the perimeter canal with an additional canal supplying water to the qocha region. Water from canals supplying water into the perimeter canal was then distributed by further surface/subterranean canals toward the Tiwanaku River.

Models of Water Management at Tiwanaku

To illustrate the hydrological function of the perimeter canal, two cases address seasonal variability in water input. The first case considers effects at the termination of a long-duration (November–March) rainy season on Tiwanaku’s perimeter canal and associated canal network; a second case considers effects of limited spring-water input during the April–October dry season. The analysis to follow utilizes location data based on aerial photographs, Google Earth imagery, and ground contour maps for hydraulic features shown in Figs. 2, 3, 4, and 6 and serves as the basis for a computational model to demonstrate hydrological features of the perimeter canal and its associated canal network. Analysis is provided through Computational Fluid Dynamics (CFD) (Flow Science, 2014) to address seasonal variability in water input. Solutions demonstrate time

history of aquifer seepage from open-face areas of the perimeter canal and water transfer/percolation within saturated/unsaturated portions of an aquifer. A porous soil aquifer model (Fig. 6) is used to demonstrate hydrological responses of the perimeter canal for different seasonal water availability cases. This CFD model shows the labels/positions of key monuments in the ceremonial core and associated canal systems identified from the data assembly. Since only segments of some canal features are available, connections are surmised to furnish a working model of canal systems to illustrate features related to the perimeter canal’s hydrological function. The canal inlets shown (J, N, and O) are sourced by canalized springs located south of the modeled area as well as (S-M) canal water directed from the Mollo Kontu canal from Corocoro spring sources. Figure 6 locates these architectural and hydrological features by letter. These include:

- A’-B’: the Tiwanaku River, flow direction A’ to B’ to Lake Titicaca
- C: canal to A’-B’
- C’: drainage/agricultural area supplied from perimeter canal seepage
- E: La Karaña residential complex
- F: Sunken (Semi-Subterranean) Temple
- G: Kalasasaya ceremonial complex
- H: Putuni Palace
- I: Connecting canal between canals L-K-L and (Akapana West) J
- K: *qocha* region supplied by canal N
- L: Akapana East canal draining *qocha* region K toward perimeter canal segment D
- M: Mollo Kontu canal linking canals O and S to the perimeter canal
- N: Supply canal to *qocha* region K
- O: Connecting canal to canal M
- P and Q: subterranean canal pair with 2° downslope to the
- Tiwanaku River; canal P runs underneath the Putuni (H)
- R: Akapana pyramid
- S: branch canal to Mollo Kontu canal (M)
- T: lateral transverse canal to L; shunt canal I to canal J and/or drain canal to perimeter canal section D

- U: Mollo Kontu monument
- W-D-V-X: perimeter canal circuit around the ceremonial core of Tiwanaku – original perimeter canal depth estimated at ~4–5 m at location D
- Y: drainage canal from V to Tiwanaku River
- Z: canal below the west side of the Akapana (R) draining toward perimeter canal segment D.

Figure 6 is composed of a subsurface porous medium aquifer that represents the soil type through which groundwater percolates. The CFD model incorporates both east-to-west and a south-to-north ground slope declinations and constitutes an approximation to all hydraulic features derived from aerial photograph, Google Earth, and ground survey data.

The perimeter canal seepage surface is the exposed canal bottom and sidewall soil area to the atmosphere. In the CFD model, the deep groundwater layer is composed of saturated soil stabilized throughout the year at ~5–6 m below the ground surface inferred from groundwater water depth measurements provided by probes inserted into drilled shafts. The perimeter canal bottom intersects the upper reaches of the deep groundwater table as evidenced by long-term water retention shown in the aerial photographs. An aquifer phreatic (vadose)-saturated layer lies above the deep groundwater layer whose depth depends on rainfall intensity and duration. For long-duration rainfall periods, this zone extends downward to recharge the deep groundwater layer. The subsurface boundary shapes and extent of these two layers is subject to change depending upon rainfall intensity, duration, as well as runoff transfer/interception during altiplano rainy and dry seasons. For post-rainy season analysis (Case 1), the phreatic zone is saturated, subject to rainfall runoff and intersecting the deep groundwater layer. In the dry season, the phreatic zone decreases in depth from the ground surface due to surface evaporation. For both cases, phreatic zone aquifer seepage occurs from the perimeter canal seepage surface to alter the local water content and shape of these layers; seepage water then accumulates into the perimeter canal

bottom. Water is supplied to the phreatic layer by capillary action from the deep groundwater zone – this effect marginally decreases the deep groundwater layer height as dry season surface evaporation continues to deplete the phreatic layer. In times of extended drought, both the phreatic layer and ultimately the deep groundwater level subside, leading to dry soil conditions to large depths.

Case 1: Post-Rainy Season Conditions

Case 1 examines typical conditions of the end of an altiplano rainy season characterized by the saturated phreatic layer extending to the deep water table upper boundary and continuous water flow through lined canals O, S, N, and J (Fig. 6) not contributing water to deep aquifer recharge. Aquifer seepage from the phreatic and deep groundwater layers arriving into the perimeter canal bottom is transferred to canals D, V, and W to X and then to the Tiwanaku River A'-B' based upon canal downslopes toward the river and accumulated water height exceeding the depth of the saturated bottom of the perimeter canal. Water in the perimeter canal's north branch is conducted to the Tiwanaku River through canal C while supplying groundwater to agropastoral systems in C' with seepage water ultimately discharged into the river. Water arriving into inlet N is conducted by canals K and L into either (or both) canals D and I into J. For downhill-flowing rainfall runoff, as well as phreatic and deep groundwater layer seepage into the perimeter canal bottom, the perimeter canal transfers water exceeding its saturated base depth to the Tiwanaku River. This effect serves as a hydraulic control limiting (or amplifying) surface runoff/groundwater transfer to raised-field systems west of Tiwanaku. A primary function of the perimeter canal was then to intercept and direct rainfall runoff from saturated east/south surface areas as well as from the ceremonial core area given that much of this area was paved and occupied by roofed buildings that limited rainfall interception. Hydrological water input/output associated with Case 1 conditions is summarized in Fig. 7 at a typical perimeter canal section. Solutions of the equations

governing porous media flow were made for aquifer percolation/water emission from the perimeter canal seepage surface with results shown in Figs. 8, 9, and 10. For saturated aquifer

conditions, velocity components $q_1 \equiv q_x$, $q_2 \equiv q_y$, and $q_3 \equiv q_z$ are given by $q_i = - (k/\mu) (\partial p / \partial x_i + \rho g \partial z / \partial x_i)$ where k is the (isotropic) specific porous material permeability, p the water pore pressure,

Hydrologic Engineering of the Tiwanaku,

and g the gravitational constant. The rightmost term represents the percolation velocity addition from gravitational forces in the vertical z -direction ($i = 3$). Figure 8 shows the perimeter canal's east-face seepage surface and adjacent ground surface moisture levels at an early, post-rainy season time; Fig. 9 shows the progression of phreatic layer depression/ground drying at a later time indicated by lower values of the fluid fraction (ff) and continued high seepage water outflow from the bottommost part of the perimeter canal seepage surface. To the east, the ground remains saturated as indicated by high fluid fraction values – as time progresses and surface drying continues, the dry area influenced by the perimeter canal's drainage increases. Fluid fraction (ff) is the water volume within porous soil media volume interstices where $ff = 1$ represents saturated soil conditions (total water infilling of open space within a unit porous volume) and $ff = 0$ represents no water present in porous volume interstices. Intermediate $0 < ff < 1$ values indicate lower water content in the porous soil. The product $ff \cdot V_f$ is the total water volume within a porous soil volume element. The vertical (z -direction) pressure gradient at the perimeter canal aquifer–air surface increases with increasing saturated soil depth, thus amplifying the seepage rate. As aquifer seepage water is directed to the bottom of the perimeter canal, top portions of the seepage surface and adjacent ground area exhibit progressive drying in time (lower values of ff) as the phreatic layer profile deflects downward (Figs. 8 and 9). Figure 10

shows the western face of the seepage surface bounding the ceremonial center area, due to lower rainfall interception and high runoff rate from paved, roofed surfaces and less seepage water (but more runoff) deposits into the perimeter canal helping to keep ceremonial core soil areas dry. As the perimeter canal depth intersects the topmost fringe of the deep groundwater layer, regulation of groundwater height was maintained throughout the rainy season by runoff drainage from saturated surface soil, phreatic and deep groundwater layer seepage above the saturated perimeter canal bottom, and water transfer from surface canals M, L, and Z to canals C, X-Y, and C' seepage to the Tiwanaku River (Fig. 7). Thus any water in the perimeter canal exceeding the height of the saturated canal bottom surface was transferred to the river to maintain deep groundwater height constant during the rainy season. This effect maintained soil foundation strength under large monumental structures by keeping the water content of deep aquifer foundation soils constant. If water is withdrawn from porous soil, soil interstices collapse under gravity/exterior loading to form a dense, compacted soil composition – this causes ground settling that affects the foundation strength/stability of massive structures. Thus the perimeter canal's hydrological function includes this structural stability effect during rainy season water input conditions. The perimeter canal path X-Y is subject to uncertainty due to construction disturbance by the modern town but sufficient perimeter canal drainage to the Tiwanaku River existed by canal

Hydrologic Engineering of the Tiwanaku,

Fig. 11 Subterranean surface fluid fraction results for the subterranean canals P and Q for Case 1 conditions under Case 1, post-rainy season conditions

C (Figs. 4 and 6), subterranean canals P and Q, and the aquifer drainage area C' to establish the perimeter canal's water collection/drainage function.

Figure 11 shows the water transport contribution of subterranean canals P and Q. Canal P lies under the floor of the Putuni and canal Q lies ~20 m west of P. Vertical pipes consisting of stacked, perforated stone disks served as water input conduits from higher secondary canals that drained water from the Putuni Courtyard/Palace into P and then toward the V segment of the perimeter canal (Fig. 6). The total extent of the drainage system in/around the Putuni and adjacent monumental areas is not presently known but excavation data indicates that an elaborate network of drainage canals lay underneath the monumental core with surface inlets feeding smaller transverse canals that delivered water to a series of larger, deeper canals. Post-rainy season sources of flushing water for the P and Q canals consisted of seepage water in perimeter canal arm W and water from Mollo Kontu canal M. As the P, Q, M, and C canals and the south–north perimeter canal bottom sloped downhill toward the river, flushing flow kept the subterranean sewer canals clean and directed wastewater toward the Tiwanaku River. Figure 11 indicates that some flow entered P and Q from W seepage and canal M water with remaining groundwater flowing into canal arms D and V which then flowed into the C' floodplain, canal C, and the P and Q subterranean extensions into the Tiwanaku River.

Case 2: Dry Season Initiation

Case 2 considers the perimeter canal under zero rainfall and continuous, but decreased, water supply from Corocoro springs into canals N, O, and M. As the dry season progressed, surface evaporation dries the phreatic zone and creates a moisture gradient between the deep groundwater capillary fringe and the shrinking phreatic layer, increasing capillary water transfer from the deep groundwater aquifer. Water at a low dry season flow rate from canal M maintains saturation of the perimeter canal's base surface, and water deposited over the saturated perimeter canal bottom flows downhill through canals D, C, and C' then to the river. Deep groundwater recession in the dry season is marginal given slow percolation water removal to lower areas, slow capillary water transfer to the phreatic zone, continued seepage accumulation into the perimeter canal's bottom, canal M water supply, and continual groundwater arrival from infiltrated rainfall from higher-elevation watershed areas. The key point is that the perimeter canal depth was intentionally set toward the top of the deep groundwater aquifer layer so that water exceeding this depth was removed to the river by canals C, Y and drainage to C' to maintain the deep groundwater height constant during dry and rainy seasons to promote structural stability of core area monuments. Figure 12 indicates ground surface moisture conditions during the dry season with low canal flow rates and limited water transfer to the phreatic layer from deep groundwater layer capillary flows. The *qocha* region of

Hydrologic Engineering of the Tiwanaku,

Hydrologic Engineering of the Tiwanaku,

Fig. 13 Representative summary diagram of water inputs/water outflows in a typical cross-section of the perimeter canal in canal leg D for dry season conditions

Hydrologic Engineering of the Tiwanaku,

Fig. 14 Case 2 fluid fraction results for the eastern section of the perimeter canal facing the ceremonial core region under dry season conditions – results indicate low seepage due to low rainfall infiltration from the paved, roofed ceremonial core region

Tiwanaku (Figs. 2, 6-K) and floodplain C' maintained dry season agropastural use due to its intersection with the deep groundwater capillary fringe zone augmented by canal M flow and seepage from the north arm of the perimeter canal. Canals P and Q had lower flushing rates from perimeter canal segment W under dry season conditions. Figure 13 summarizes dry season

water input/output flows at a typical perimeter canal cross-section segment. Figure 14 indicates a lower level of seepage into perimeter canal arm D as the dry season progresses; the phreatic layer is nearly absent indicating further ground surface dryness. In total, the dry season deep groundwater water content/height is maintained from continued, but reduced, canal M flow into the

perimeter canal, phreatic zone seepage water outflows, and percolation water transfer from adjacent watershed areas. As the dry season progresses, canals contain diminished spring flow and the phreatic layer continues to lose water from evaporation and drainage. As a result, phreatic layer hydrostatic pressure diminishes, resulting in more of the perimeter canal seepage surface participating in leakage but at a lower seepage rate than that for Case 1 conditions as lower Fig. 14 ff values indicate.

Conclusion

The perimeter canal served to increase drying of Tiwanaku's ceremonial core and nearby urban ground surfaces while providing foundational stability for its monumental structures. Subterranean canals P, Q served the hygienic requirements of the Putuni and Kerikala structures by providing flushing water from accumulated perimeter canal seepage water supplemented by canal M flow directed toward the P inlet. Each major monumental complex maintained an intricate drainage system that simultaneously served practical and ritual purposes. While the Akapana served ritual functions (Kolata, 1993, 1996, 2003), its drainage network limited rainfall infiltration into its internal soil fill to preserve its structural integrity as hydrostatic forces created by internal water seepage would have destabilized its stone-faced construction. Canal M flow, plus seepage water deposited into the perimeter canal bottom, is balanced by outflow canal and seepage paths C, C', X-Y, and P, Q (Figs. 7 and 13). A series of canals O, N located south of the perimeter canal directed water to the *qocha* complex K with excessive water from canal K diverted by canals I → J → L to the river thus protecting agropastoral area K from canal overspillage. Additionally, the perimeter canal regulated the deep groundwater height throughout seasonal water availability change to keep the foundations of Tiwanaku's monumental compounds secure from ground settling. These water management constructions reinforce the conclusion that Tiwanaku engineers envisioned

a drainage network involving the perimeter canal to control site ground soil moisture levels to improve environmental living conditions and maintain the structural stability of the city's monuments. Thus the perimeter canal appears to be the linchpin of an intricate hydrological network that regulated water flow/drainage during seasonal change.

Prior studies focused on Tiwanaku's hinterland demonstrated an understanding of hydraulics/hydrology to develop intensive groundwater-dependent, raised-field farming systems. Present research demonstrates the urban center of Tiwanaku incorporated similar technologies employing the perimeter canal as the central element. The technical innovations applied to advance progress within Tiwanaku society offer perspectives on the societal organization and the idea laboratory behind their engineering creations and demonstrate that knowledge of the three-dimensional manipulation of surface and groundwater by the Tiwanaku provides a further consideration in assessing New World engineering science.

Ibn ‘Abbād

Zeina Matar

Abū al-Qāsim Ismā‘īl Ibn ‘Abbād Ibn al-‘Abbās Ibn ‘Abbād Ibn Ahmad Ibn Idrīs, also known as Kāfī al-Kufāt, and al-Šāhib, was a famous vizier and man of letters of the Buwayhid period. There is disagreement about his place and date of birth, but he was probably born at Iṣṭakhr on 16 Dhū’l-qa‘da 326/14 September 938. His family included high dignitaries, and his own father had been a *kātib* (clerk) and then vizier, or minister of state, under the Buwayhid Prince Rukn al-Dawla (r. 35/946–366/976).

Ibn ‘Abbād himself became the disciple and secretary of Abū’l-Faḍl Ibn al-‘Amīd (d. 360/970), the father of the Buwayhid vizier Abū’l-Faṭḥ Ibn al-‘Amīd (b. 337/948–9). His close relationship to the Buwayhid *amīrs* (princes) is said to have begun in 347/958, when he accompanied Mu‘ayyid al-Dawla (reigned 366/976–373/983) to Baghdad as a clerk. He was later confirmed in this office when Mu‘ayyid al-Dawla became governor of Isfahan. Ibn ‘Abbād’s career took a more significant turn when he was appointed vizier, replacing Abū’l-Faṭḥ Ibn al-‘Amīd.

Ibn ‘Abbād served two rulers: Mu‘ayyid al-Dawla and Fakhr al-Dawla (reigned 373/983–387/997). The main source for the

study of his vizierate remains the volume of the *Rasā’il* (‘Azzam, 1946), which is a collection of administrative pieces, appointment, and other official letters by Ibn ‘Abbād. According to the sources, the personality of Fakhr al-Dawla was not really compatible with that of Ibn ‘Abbād, although he recognized the latter’s administrative skills and talents. When Ibn ‘Abbād died on 24 Safar 385/30 March 995, Fakhr al-Dawla confiscated his property, and from that time onward, no other member of his family was to be appointed to a high official position.

Ibn ‘Abbād was not only a statesman and a politician, but he was also a talented writer whose works cover a very wide spectrum. In their article in the *Encyclopedia of Islam*, Claude Cahen and Charles Pellat give a classification of his works: dogmatic theology, history, grammar and lexicography, literary criticism, poetry, and belles-lettres.

In Abū Ḥayyān al-Tawḥīdī’s *Mathālib al-Wazīrayn*, a comprehensive list of Ibn ‘Abbād’s works is given. Some of the most important are:

- *Kitāb al-Muḥīt bi-‘l-lughā* (The Comprehensive Treatise About Language) in ten vols
- *Kitāb Dīwān rasā’ilihi* (Collection of Letters) in ten vols
- *Kitāb al-Kāfī. Rasā’il* (The Book of al-Kāfī [that which is sufficient]. Letters [or Correspondence])

- *Kitāb al-Aʿyād wa-faḍāʾil al-Nowrūz* (The Book of Feasts and the Excellent Qualities of New Year's Day)
- *Kitāb al-Wuzarāʾ* (The Book of Viziers)
- *Kitāb Dīwān Shiʿr(ihi)* (Collection of Poetry)

In the *Yatīmat al-dahr* (III, 204), al-Tha ʿālībī commented on a *Risāla* on medicine said to have been written by Ibn ʿAbbād:

I found that it combined beauty of style, elegance of expression, and mastery of the subtleties and particularities of medicine, and it showed that he was thoroughly familiar with this science, and had a penetrating knowledge of its intricacies.

Ibn ʿAbbād often inspired very contradictory opinions and feelings as is shown by Abū Ḥayyān al-Tawḥīdī's hostility on the one hand, and by al-Tha ʿālībī's praise and admiration on the other. However, regardless of personal like or dislike, he certainly was a highly exceptional personality in Muslim history. Maybe one can refer to him as a "patron-vizier", a talented individual who had the ability to mix politics and literature, and a poet whose court once counted as many as 23 poets.

Ibn Al-ʿArabī

William C. Chittick

Stony Brook University, New York, NY, USA

Muḥyī al-Dīn ibn al-ʿArabī is one of the most influential Muslim thinkers of the past 700 years. Born in Murcia in present-day Spain in 1165, he set out for the western lands of Islam in 1200, traveled in the Arab countries and Turkey, and, in 1223, settled in Damascus, where he lived until his death in 1240. He wrote voluminously and attracted the attention of scholars and kings during his own lifetime. His magnum opus, *al-Futūḥāt al-makkiyya* (The Meccan Openings) – inspired sciences that were “opened” up to his soul during his pilgrimage to Mecca – will fill some 15,000 pages in its new edition. His most widely studied work, *Fuṣūṣ al-ḥikam* (The Bezels of Wisdom), is a short explication of the various modalities of wisdom embodied by 28 of God's prophets, from Adam to Muhammad.

Ibn al-ʿArabī's writings investigate every dimension of Islamic learning, from the *Qurʾān* and the *Ḥadīth* (the sayings of Muḥammad) to grammar, law, philosophy, psychology, and metaphysics. His basic intellectual project was to illustrate the unity of all human endeavors and the underlying, interrelated functions of all human thinking. He cannot be classified as a philosopher, theologian, scientist, or jurist, though his works address most of the basic epistemological issues of these disciplines. He saw himself as an inheritor of the wisdom of the prophets, but one who was given the duty of explaining this wisdom in the subtlest intellectual discourse of the day – at a period that is looked back upon as the high point of Islamic learning. He provides no system, but rather a unified vision that is capable of spinning off innumerable systems, each of them appropriate to a given field of learning or level of understanding. He offers many ways of approaching the basic questions of human existence, such as the nature of reality itself, the role of God, the structure of the cosmos

and the human psyche, the goal of human life, and the relationship of minerals, plants, and animals to other creatures. In short, he provides basic patterns for establishing complex systems of metaphysics, theology, cosmology, psychology, and ethics.

Ibn al-ʿArabī was followed by a number of major thinkers who systematized his “openings” in various ways, depending upon their own orientations and intellectual contexts. The diverse interpretations given to his works are especially obvious in a series of over 100 commentaries that have been written on his *Bezels of Wisdom* from the thirteenth century down to modern times. His stepson Ṣadr al-Dīn Qūnawī (d. 1274) had probably the keenest philosophical mind among Ibn al-ʿArabī’s followers. Qūnawī in turn trained many disciples, several of whom wrote widely influential works. Saʿīd al-Dīn Farghānī (d. 1296) provided systematic expositions of the teachings of both Qūnawī and Ibn al-ʿArabī in Arabic and Persian. Fakhr al-Dīn ʿIrāqī (d. 1289) was a poet who wrote a delightful summary of Qūnawī’s teachings in mixed Persian prose and poetry that helped popularize Ibn al-ʿArabī’s teachings. Muʿayyid al-Dīn Jandī (d. ca. 1300) wrote in Arabic the first detailed commentary on Ibn al-ʿArabī’s *Bezels of Wisdom*. The intellectual tradition established by Ibn al-ʿArabī and Qūnawī gradually merged with various branches of Islamic philosophy, yielding a wide range of intellectual perspectives that dominated the Islamic wisdom tradition down to the coming of Western colonialism.

In order to grasp Ibn al-ʿArabī’s importance for the history of scientific thought in Islam, one needs to understand his basic accomplishment, which was to establish an honored place in the Islamic intellectual tradition for supra-rational knowledge. From their inception in the eighth and ninth centuries, the mainline schools of theology and philosophy in Islam had endeavored to understand the Quranic revelation on the basis of rational modes of investigation taken over from the Greek heritage. Parallel to this, there developed a more practical, existential approach that found the goal of human life in direct experience of the presence of God. This second approach,

which came to be called by the umbrella term “Sufism,” laid stress upon supra-rational modes of knowledge that are collectively known as *kashf* (unveiling), i.e., the lifting of the veils that separate the human soul from God. Unlike some Sufis, Ibn al-ʿArabī was not opposed to acknowledging the authority of reason. However, he maintained that unveiling was a higher form of knowledge, because it grows out of the unmediated perception of God’s actuality. In Ibn al-ʿArabī’s way of looking at things, reason tends innately to divide and discern. It eliminates connections between God and the cosmos and understands God as distant and transcendent. In contrast, unveiling works by seeing sameness and presence; hence, God is perceived as near and immanent. Perfect knowledge of God and of reality as a whole depends upon a happy balance of reason and unveiling. Only through this balance can God be perceived in appropriate modes as both absent and present, near and far, transcendent and immanent, and wrathful and merciful. Ibn al-ʿArabī’s works are devoted largely to explaining the vast range of these appropriate modes.

The long-term effect of the marriage between reason and unveiling effectuated by Ibn al-ʿArabī is symbolized by his meeting when still a boy – of perhaps 15 years – with the philosopher Ibn Rushd (Averroes d. 1198). Ibn al-ʿArabī had already experienced the opening of the unseen worlds, and Ibn Rushd, who was a friend of his father, had asked to meet him. In the brief exchange that took place, Ibn Rushd asked if unveiling and reason achieved the same goals. Ibn al-ʿArabī replied, “Yes and no.” Then, in cryptic language, he affirmed that reason was a valid route to achieve knowledge of the nature of things, but he denied that it exhausted the possibilities of human knowing. In the West, the teachings of Ibn Rushd were employed to help establish nature as an autonomous realm of intellectual endeavor. Under the discerning eye of reason, God was abstracted from perceived reality, eventually becoming a hypothesis that could be dispensed with. The world of nature was now the proper site for rational analysis and dissection, and the result has been the ever-increasing fragmentation of human knowledge, with a total

divorce between science and ethics. In contrast, Ibn Rushd was forgotten in the Islamic world, but Ibn al-‘Arabī and his followers succeeded in establishing a harmony between reason and unveiling. Hence, Muslim intellectuals were never able to conceive of nature as a realm cut off from God. If God is present in all things, then the ethical and moral strictures that he establishes through revelation need to be observed at every level. It becomes impossible to investigate the natural world without at the same time investigating its relationship with God and recognizing the moral and ethical demands that this relationship entails.

Ibn al-‘Arabī’s career and teachings exemplify the dimensions of Islamic learning. The worldview to which he gave detailed expression provided a perspective from within which Muslim intellectuals were able to answer the deepest questions of the human mind. Ibn al-‘Arabī’s achievements contributed to an intellectual equilibrium that refused to subordinate the spiritual demands of human beings to corporeal demands and that gradually established a vast framework within the context of which the intellectual disciplines came to be ever more united and interrelated. This holistic perspective on knowledge in turn prevented the fragmentation of the Islamic worldview and allowed no room for “declarations of independence” by specific schools of science or philosophy. Given that ethics, morality, and spiritual development lay at the heart of this perspective, it was impossible to divorce any branch of science or learning from these concerns.

Ibn Al-A‘lam

Raymond Mercier

Ibn al-A‘lam, Abū’l-Qasim ‘Alī ibn ‘Isa al-Husain, al-‘Alawī, al-Sharīf was a tenth century astronomer, apparently established in Baghdad. The year of his death is recorded by Ibn al-Qifṭī as 375/985. The ► **Zīj** (astronomical handbook with tables) which he wrote is lost, but substantial information about it may be gleaned from notices in the work of other astronomers. His work was patronized by the Būyid ruler ‘Aḡūd al-Dawla but suffered from lack of support in the disturbed period which followed his death in 372/982.

A near contemporary, the great astronomer Ibn Yūnus of Cairo, reports that Ibn al-A‘lam had fixed the length of the year as 365; 45, 40, 20 days, determined the position of Regulus (α Leonis) in the year 365/975-6 as 15; 6 Leo, and also fixed the rate of precession, 1° in 70 Persian years. He remarks that Ibn al-A‘lam

was known everywhere for the exactitude of his observations and the extent of his geometrical knowledge.

► **Al-Bīrūnī** in his work *Tamhīd al-mustaḡarr li-taḥqīq ma'nā al-mamarr* (On Transits) gives the name of his *Zīj* as *al-ʿAdūdī*, and incidentally provides values for the radius of the epicycles for each of the planets.

In spite of the loss of the *Zīj* full information about its parameters may be obtained from two sources compiled in the fourteenth century, the Persian *Zīj-i Ashrafī*, and an anonymous Arabic collection known as the *Dastūr al-Munajjimīn*. Information is also available from Greek sources, in which Ibn al-Aʿlam is referred to as Alim (ʿΑλημ). The Greek manuscripts are of the fourteenth and fifteenth centuries, but they preserve texts older than the Persian and Arabic compilations. These include *scholia* to the *Almagest* datable to AD 1032 which refer to tables composed for the Greek calendar from the work of Ibn al-Aʿlam, as well as two horoscopes for the years AD 1153 and AD 1162 which have been calculated from such tables, apparently for the Emperor Manuel Comnenus. The tabulation of the equations indicates that the technique of “displacements” was used in order to provide values of the equations which were always positive.

Ibn al-Bannā'

Emilia Calvo

Ibn al-Bannā' al-Marrākushī, Abū-i-ʿabbās Aḥmad ibn Muḥammad ibn ʿUthmān al-Azdī was born in Marrakesh, Morocco on 29 December 1256 and died, probably in Marrakesh, in 1321. He studied the Arabic language, grammar, the *Qu'rān*, *Ḥadīth* (commentaries of the prophet), and also mathematics, astronomy, and medicine; but his fame is due to his knowledge of mathematics. His teachers in this field were Muḥammad ibn Yaḥyā al-Sharīf, Abū Bakr al-Qallūsī, and Abū ʿAbd Allah ibn Makhluḥ al-Sijilmāsī. He also studied medicine with al-Mirīkh.

Among his disciples were al-Lajāʿ, teacher of Ibn Qunf ūdh, Muḥammad ibn Ibraḥīm al-Abūlī, Abū-l-Barakāt al-Balāfiqī, and Ibn al-Najjār al-Tilimsānī.

He is credited with having written more than 80 works. Among them are an introduction to Euclid, a treatise on areas, an algebra text, a *Kitāb al-anwāʾ* (about asterisms and stars used in meteorology and navigation), an almanac, two abridgements of treatises by ► **Ibn al-Zarqāllu** on the use of the *Ṣafṭḥas* (astrolabes) *zarqāliyya* and *shakkāziyya* entitled, respectively, *Risālat al-ṣafṭḥa al-mushtaraka ʿalā al-shakkāziyya* (Epistle on the Shakkāziyya Plate), in 23 chapters, and *Taqbīl ʿalā risālat al-ṣafṭḥa al-zarqāliyya* (Epistle on al-Zarqālī's Plate). However, his two most important works are the *Minhāj* and the *Ṭalkhīṣ*.

The *Kitāb minhāj al-tālib li taʿdīl al-kawākib* (The Way of Him Who Seeks the Equation of the Planets) is a very practical book for calculating astronomical ephemerides. This ► **zīj** (astronomical handbook with tables) is based on the one by Ibn Ishāq. The two of them are highly dependent on Ibn al-Zarqāllu's astronomical theories.

The *Talkhīṣ aʿmāl al-ḥisāb* (Summary of Arithmetical Operations) was widely diffused in the Arabic world because of its conciseness, which makes it easy to memorize. ► [Al-Qalaṣādī](#), among others, wrote an important commentary on it. A different version of this work, more extensive and complete, has been edited recently by Saidan (1984) under the title *Al-maqālāt fī ʿilm al-ḥisāb li-Ibn al-Bannāʾ* (The Treatises on the Science of Computation by Ibn al-Bannāʾ). The procedures found in the *Talkhīṣ* are studied here in a more detailed way.

Ibn al-Bayṭār

Emilia Calvo

Ibn al-Bayṭār al-Mālaqī, Ḍiyāʾ al-Dīn Abū Muḥammad ʿAbdallāh ibn Aḥmad, was a pharmacologist born in Málaga, Spain at the end of the twelfth century (ca. AD 1190–1248). He studied in Seville with Abū-l- ʿAbbās al-Nabātī, ʿAbdallāh ibn Šāliḥ, and Abū-l-Hajjāj. He was interested in the works of al-Ghā fī qī, al-Zahrāwī, ► [al-Idrīsī](#), Dioscorides, and Galen.

Around AD 1220 he migrated to the East and, in 1224, arrived in Cairo where he was named chief herbalist by the Ayyūbid Sultan al-Kāmil. He traveled through Arabia, Palestine, Syria, and Iraq. Ibn Abī Uṣaybiʿa was one of his followers and left a mention of his teacher full of praise in his *ʿUyūn*.

Among Ibn al-Bayṭār's works we can mention *Al-Mughnī fī l-adwiya al-mufrada* (The Complete Book on Simple Drugs), dedicated to al-Kamil's son, Sultan al-Šāliḥ and dealing with the simple medicines, and *Al-Jāmiʾ li-mufradāt al-adwiya wa-l-aghḍhiya* (Compendium of Simple Drugs and Food), which enumerates alphabetically some 1,400 animal, vegetable, and mineral medicines, as well as some 150 authorities including ► [al-Rāzī](#) and Ibn Sīnā.

Ibn al-Bayṭār's main contribution is the systematization of the discoveries made by the Arabs during the Middle Ages in this field. He was also concerned with synonymy, finding the technical equivalents between the Arabic and Persian, Berber, Greek, Latin, and Romance languages. The *Jāmiʾ* had great influence in the Near East, but less in the West. Andrea Alpago used it in his works on Ibn Sīnā.

Other works of Ibn al-Bayṭār, less known than the aforementioned two, are *Mizān al-ṭabīb* (The Measure of the Physician), *Risāla fī l-aghḍhiya wa l-adwiya* (Treatise on Food and Medicines), *Maqāla fī l-laymūn* (Treatise on the Lemon), and *Tafsīr kitāb Diyusqūrdīs* (Explanation of Dioscorides' Book) in which he inventories

550 medicines found in the first four books of Dioscorides.

Ibn al-Hā’im

Julio Samsó

‘Abd al-ḥaqq al-Ghāfiqī al-Ishbīlī is known as Ibn al-Hā’im. He was an Andalusian astronomer, probably from Seville. He dedicated (ca. 1204) his very important *al-Zīj al-Kāmil fī l-Ta’ālīm* (The Perfect Handbook on Mathematical Astronomy) to the Almohad Caliph Abū ‘Abd Allāh Muḥammad al-Nāṣir (1199–1213). This work, which is extant in a unique and incomplete manuscript in the Bodleian Library at Oxford

University, was influential in the Maghreb and contributed to the development there of a new kind of astronomy in the Andalusian tradition. As a ► *zīj* (astronomical handbook with tables), it is exceptional in Western Islam, because it contains a highly technical and complete exposition of Ptolemaic astronomy with geometrical demonstrations, and not a simple set of instructions for the use of the tables. It also conveys new information on the astronomical works of the Toledan school of the eleventh century, the main representative of which was Ibn al-Zarqāllu/Azarquiel (d. 1100), as well as new planetary parameters. Ibn al-Hā’im appears as a defender of Zarqāllian orthodoxy and harshly criticizes ► *Ibn al-Kammād* (fl. beginning of the twelfth century) for his modifications of Ibn al-Zarqāllu’s doctrines. Ibn al-Hā’im’s *zīj* contained numerical tables (three have been preserved in the *zīj* of Ibn Ishāq, who flourished in Tunis at the beginning of the thirteenth century) but an incomplete copy must have circulated early for ► *Ibn al-Raqqām* (d. 1315) states that Ibn al-Hā’im did not include any tables in his work.

Ibn Al-Haytham (Alhazen)

Roshdi Rashed

Among the mathematicians of classical Islam, few are as famous as al-ḥasan ibn al-ḥasan ibn al-Haytham (Alhazen in the Latin West).

A physicist and astronomer as well as mathematician, he quickly gained a wide reputation, first in Arabic, in the Islamic East as well as the Islamic West, and then from the translations of his works in optics and astronomy into Latin, Hebrew, and Italian.

But his renown, completely justified by the importance of his contributions and especially of the scientific reforms accomplished in them, contrasts singularly with the paucity of information we have on the man, his teachers, or his scientific milieu. Also, the significance of his works surrounded the man with the aura of a legend. Sources available to us consist of narratives recounted by ancient bibliographers where legend becomes mixed up with the rare historical evidence. These same narratives are precisely what modern bibliographers continue to reproduce partially or totally until today. After a critical reading of these sources, very little information remains: born in Iraq, most likely in Bassorah, sometime in the second half of the tenth century, Ibn al-Haytham arrived in Cairo, under the reign of Faṭimid al-ḥākim. He proposed a hydraulic project to control the waters of the Nile, but it was rejected by the Caliph. He continued to live in Cairo until his death, after 432/1040.

From the thirteenth century until today, biographers have confused al-ḥasan ibn al-Haytham with Muḥammad ibn al-Haytham, a philosopher and theorist of medicine who lived in Baghdād at the same time. This confusion, due undoubtedly to similarity of the two names of these contemporary authors, is serious as it brings into question the authenticity of certain writings attributed to al-ḥasan ibn al-Haytham.

Biobibliographers, notably al-Qifṭī, cite 96 titles of Ibn al-Haytham, not all of which have survived. Half of his writings are in the field of mathematics, 14 on optics, including the authoritative and voluminous *Kitāb al-Manāẓir* (Book of Optics), 23 on astronomy, 2 in philosophy (1 on the *Place* and the other on the *Indivisible Part*), 3 on statics and hydrostatics, 2 on astrology, and 4 on various other topics. This accounting shows clearly that Ibn al-Haytham grappled with all the mathematical sciences of

that time, or at least the most advanced part of this discipline. We will see that he was always at the leading edge of research or at the culmination of one tradition and the beginning of a new period. It is precisely this quality which distinguishes his contributions. Ibn al-Haytham lived at a privileged time, his work following a century of intense research in these fields by eminent scholars such as the ► [Banū Mūsā](#), ► [Thābit ibn Qurra](#) and his grandson ► [Ibrāhīm ibn Sinān](#), al-Qūhī, and ► [Ibn Sahl](#), to name a few. We will now briefly examine the principal aspects of his research.

Mathematics

Ibn al-Haytham's mathematical research was particularly in the field of geometry and not of algebra. Ancient biobibliographers attributed a book on algebra to him, but it has not survived. From the outset, geometers wanted to combine closely the study of the positions of figures and their metric properties: in other words, to combine the geometry of Apollonius with that of Archimedes. This combination is not a static synthesis, but a new organization of geometry which possessed a real heuristic value. Already initiated by al-ḥasan ibn Mūsā and followed by Thābit, this work led to the study of geometric transformations and of projective methods. It was this work which Ibn al-Haytham developed further in his own geometrical studies.

The contributions of Ibn al-Haytham in geometry can be divided into several groups, the most important of which are in infinitesimal mathematics and the theory of conic sections and their applications. He composed 12 treatises on infinitesimal mathematics and then on conic theory. To those can be added a third area in which Ibn al-Haytham takes up several problems relating to the foundations of mathematics and their methods in his treatise *Maqāla fī 'l-taḥlīl wa 'l-tarkīb* (On Analysis and Synthesis), his *Kitāb fī al-ma 'lūmāt* (On the Known Things), his *Sharḥ Uṣūl Uqlīdis fī 'l-handasa wa 'l-'adad wa talkhīṣuhu* (Commentary on the *Elements* of

Euclid), and his *Kitāb fī Ḥall shukūk Kitāb Uqlīdis fī 'l-uṣūl wa-sharḥ ma'ānīh* (Solutions to Doubts) again concerning Euclid. In these books, he deals as much with the constitution of a new discipline, a kind of proto-topology, as with the theory of the demonstration within the difficulties raised by the fifth postulate of Euclid, or with the theory of parallels. Ibn al-Haytham also edited an important paper on number theory, four treatises on arithmetic, and the same number on practical geometry.

Of the 12 papers on infinitesimal mathematics, only 7 have survived. The first three are devoted to the study of lunes and the quadrature of a circle. Note that the calculation of the area of lunes involves the calculation of sums or differences of areas of sectors or of triangles, the comparison of which has recourse to that of the ratio of angles or of the ratio of segments. In the most important of the three papers, Ibn al-Haytham begins by setting up four lemmas, the results of which demonstrate the role of the function f , defined as

$$f(x) = \frac{\sin^2 x}{x}$$

in the study of lunes.

In his study *Tarbī' al-dā'ira* (On the Quadrature of a Circle), he examines the relationship between proving the existence of a magnitude or a property and the question of effectiveness of its construction.

Other treatises on infinitesimal mathematics deal with the volume of a solid curve: *Misāḥat al-mujassam al-mukāfi'* (The Measurement of a Paraboloidal Solid) and *Misāḥat al-kura* (The Measurement of a Sphere). In calculating the volume of a paraboloid, Ibn al-Haytham deals rapidly with the volume of a revolving paraboloid, which had already been studied by ► [Thābit ibn Qurra](#) and al-Qūhī. He then moves on to his own invention: how to calculate the volume of a paraboloid obtained from the rotation of a parabola around its ordinate. He shows that this volume is 8/15 of the volume of the circumscribed cylinder. His calculation is equivalent to that of the integral

$$\pi \int_a^b k^2 (b^2 - 2b^2 y^2 + y^4) dy = \frac{8}{15} \pi k^2 b^5 = \frac{8}{15} V,$$

with V being the volume of the circumscribed cylinder.

Ibn al-Haytham proceeded in this study with the help of the method of integral sums, which he also applied in calculating the volume of a sphere. In order to do this calculation, Ibn al-Haytham generalized the proposition X-1 of Euclid's *Elements*. He devoted the seventh paper in this group to that. This group includes an important treatise devoted to isoperimetric and isepiphane problems. It was the most advanced mathematical work of its time and for several centuries following. In it, to study these *extrema*, he had to undertake the first substantial research on the theory of a solid angle. Moreover he combined both a projective method and an infinitesimal method.

Ibn al-Haytham's second group of mathematical writings dealt with the theory of conic sections. He was well acquainted with the Conics of Apollonius and had copied them in his own hand, so he knew that, in Greek, the eighth and last book was lost. He tried to reconstruct the book according to the indications of Apollonius. In addition to his writings on conics, he applied the theory of the intersection of conics to the resolution of problems which cannot be constructed with a compass or ruler, problems either passed down (for example, the regular heptagon) or posed by him (for example, the solution of a solid arithmetic problem). Ibn al-Haytham was one of the first mathematicians who insisted on demonstrating the existence of the point of intersection of two conics in these last examples.

It is impossible in this space to explicate the mathematical results of Ibn al-Haytham's work. But let us simply note his expression of what is called Wilson's theorem, and the converse of Euclid's theorem for perfect numbers.

Indeed, in the course of solving the problem called the Chinese Remainder, he stated Wilson's theorem, which can be written as:

n is prime

$$(n-1)! - 1 \pmod{n}.$$

As for the converse of Euclid's theorem of perfect numbers, he tried to show that any even perfect number is in Euclidean form, in other words in the form $2^p(2^{p+1} - 1)$ with $(2^{p+1} - 1)$ prime.

Optics

A brief look at the work of Ibn al-Haytham on optics reveals not only its revolutionary nature but also its comprehensiveness, touching all the known branches of optics: optics in its proper sense in his *Book on Optics* and his *Discourse on Light*; catoptrics, notably burning mirrors (parabolic and spherical burning mirrors); dioptrics, in *al-Kura al-muḥriqa* (The Burning Sphere); and meteorological optics in *Daw' al-qamar* (The Light of the Moon), *Aḍwā' al-kawākib* (The Light of the Stars), *Fī Ṣūrat al-kusūf* (On the Shape of the Eclipse) and *al-Hāla wa-qaws quṣaḥ* (The Halo and the Rainbow). With this extension, Ibn al-Haytham modified the meaning of optics. Optics is not any more reduced to a theory of direct vision, a geometry of the gaze with which a theory of vision is associated, but also bears significantly on the theory of light, its propagation, and its effects as a material agent. This leads us to the revolution accomplished by Ibn al-Haytham in optics and more generally in physics.

Ibn al-Haytham sought to bring about a program of reform, which led him to take up a whole range of different problems. The basic aspect of this reform was to clarify the difference between the conditions of the propagation of light and the conditions of the vision of objects. This led, on the one hand, to giving physical support to the rules of propagation – making a firm mathematical analogy between a mechanical model of the movement of a solid ball thrown against an obstacle and that of light – and on the other hand to proceeding geometrically at all times, both by observation and by experimentation. Optics consisted henceforth of two parts: one, a theory of vision and the associated physiology of the eye

and psychology of perception, and the other, the theory of light to which are linked geometric optics and physical optics. The organization of the *Optics* reflects this new situation: there are chapters devoted entirely to propagation, such as the third chapter of the first book and books IV to VII; others deal with vision and related problems. This reform also resulted in the emergence of new problems, such as Alhazen's problem in catoptrics, the examination of the spherical lens and the spherical dioptr, not only as burning instruments but also as optical instruments in dioptrics, and to experimental control, viewed as much as a general practice of investigation as the norm of a proof in optics, and more generally in physics. Let us now take a quick look at how this reform in optics was carried out.

Ibn al-Haytham rejected any doctrine of a ray stemming out from the eye, called a visual ray, in order to defend the intromissionist theory of visible forms. But unlike the intromissionists of antiquity, he did not believe that objects sent off "forms" or totalities which emanated from the visible under the effect of light. He saw them rather as forms reducible to their elements: a ray emanating toward the eye from every point of a visible object. Looked at thus, the eye becomes a simple optical instrument. Ibn al-Haytham then explained how the eye perceives the visible with the help of its rays emitted from all points. In the *Optics* he devotes the first three chapters to the foundations of this theory. In the three following chapters, he deals with catoptrics. The seventh and last chapter is devoted to dioptrics. His theories rest on two qualitative laws of refraction and on several quantitative rules, all controlled experimentally with the help of an instrument which he designed and built himself. The two qualitative laws, known to his predecessors Ptolemy and ► [Ibn Sahl](#), can be stated as follows:

1. The incident ray, the normal at the point of refraction, and the refracted ray are in the same plane; the refracted ray gets closer (respectively, far away) from the normal, if light passes from a milieu less (respectively, more) refringent to a milieu more (respectively, less) refringent
2. The principle of inverse return

Instead of pursuing the path opened up by his predecessor Ibn Sahl, Ibn al-Haytham returned to a study of angles in order to establish the quantitative rules. He devoted a substantial part of the seventh book to a study of the refracted images of an object, notably if the surface of separation of two milieus is either planar or spheric. It was in the course of this study that he fixed his attention on the spherical diopter and the spherical lens. He returned to the spherical lens in his treatise *On the Burning Sphere*, one of the high points of research in classical optics, in order to improve upon certain results that he had already obtained in his *Optics*. This treatise was the first deliberate study on the spherical aberration for parallel rays falling on a glass sphere and giving off two refractions.

Astronomy

By their number, their thematic variety, the power of the analysis they show, and by their results, the works of Ibn al-Haytham in astronomy yield nothing to his works in mathematics or optics. It should be noted only that an elementary treatise of Muḥammad ibn al-Haytham, the *Commentary on the Almagest* is often erroneously attributed to Ibn al-Haytham. The attribution of the book *On the Configuration of the Universe* to him is also doubtful. The authentic works of Ibn al-Haytham have not yet been seriously studied, *a fortiori*, apart from a few rare and particular contributions, such as the *Samt al-ibla bi-al-ḥisāb* (Determination of the Direction of Mecca by Calculation). It remained for subsequent astronomers, notably al-ʿUrdī, one of the founders of the school of Marāgha, to recognize their debt to Ibn al-Haytham's book *al-Shukūk ʿalā Baṭlamyūs* (Doubts on Ptolemy). Before assessing his contribution in astronomy, we must wait until his books have received the editing and study that they deserve.

The impact of the work of Ibn al-Haytham varies according to the field. In mathematics, his influence can be seen in the works of Ibn Hūd, al-Khayyām, ► [Sharaf al-Dīn al-Ṭūsī](#), and

al-Samaw'al, among others. But we do not know anything of successors who might have tried to follow up on his research on lunes, the solid angle, or the measurement of figures and solid curves. In optics, the Latin translation of his *Optics* (under the title *Perspectiva* or *De Aspectibus*, reedited in 1572 under the title *Opticae Thesaurus*) and his treatise *On Parabolic Burning Mirrors* provided a basis of research for centuries of scholars such as Witelo, Roger Bacon, J. Peccham, Frederick of Fribourg, Kepler, and Snell, among many others. In Arabic, there is the commentary of Kamāl al-Dīn al-Fārsī. Finally in astronomy, there is the work of al-ʿUrdī which shows the influence of his work. It is too soon to measure the impact of the writings of Ibn al-Haytham on his successors in this field also, but they appear to be immense.

Ibn al-Kammād

Julio Samsó

Abū Jaʿfar Ahmad ibn Yūsuf ibn al-Kammād was an Andalusian astronomer who flourished in Cordoba toward the end of the eleventh century and the first half of the twelfth. He was probably a direct disciple of Ibn al-Zarqāllu/Azarquiel (d. 1100) as well as the student who helped him in observations made in Cordoba during his last years. He compiled three sets of astronomical tables (*zīj*es) of which only one (*al-Muqtabis*) is extant in a Latin translation made by Johannes of Dampno in Palermo (1262). In it he appears as a follower of the Zarqallian tradition, although he often corrects his master's parameters. Toward 1204, ► [Ibn al-Hā'im](#) makes a strong criticism of one of his other two *zīj*es (*al-Amad' alā' l-abad*, Valid for all Eternity) because of his departures from Zarqallian orthodoxy. Also extant, in Arabic, is a small astrological work in which Ibn al-Kammād studies the problem of the length of human pregnancy and the determination of the exact moment of the conception.

His work was influential in late Maghribean and Egyptian astronomy, for quotations and tabular materials from his *zīj*es appear in the thirteenth century ► [zīj](#) of ► [Ibn Ishāq al-Tūnisī](#) in Abū'l-ḥasan 'Alī al-Marrākushī's treatise on *mīqāt* (Astronomy Applied to Muslim Worship) and in a fourteenth century anonymous Egyptian treatise on the same topic.

Ibn al-Majūsī

Sami K. Hamarneh

Abū'l-ḥasan 'Alī ibn al-'Abbās ibn al-Majūsī was considered one of the leading Muslim physicians of his time. He was of Zoroastrian ancestry, and therefore called the Magian, and he is known in Latin as Haly 'Abbās. He was born in the old Persian city of Arrajān, in the southwest of Iran,

at the end of the first quarter of the tenth century. He studied medicine under a leading medical tutor (*shaykh*) named Abū Māhir Mūsā ibn Yūsuf ibn Sayyār, who died ca. AD 983.

When he had developed a reputation for excellence and skill, Ibn al-Majūsī was invited to become a physician-in-ordinary at the palace of King ‘Aḍud al-Dawlah Fannā Khusraw, who reigned from AD 949 to 983 in Shīrāz. He was the Buwayhid Shāh who founded al-‘Aḍudī Bīmāristān, the famous hospital in Baghdad that lasted for almost three centuries. In that period, the Buwayid Dynasty’s power and glory reached their apex.

In recognition of the King’s generosity and patronage to the sciences and the arts, Ibn al-Majūsī dedicated his medical encyclopedia, *Kāmil al-Ṣinā‘ah al-Ṭibbīyah*, known also as *Kitāb al-Malikī* (Latin *Liber regius*, presented to the King’s royal library) in Shīrāz.

The book comprises two parts, the theoretical and the practical, each of which has ten treatises. It brought together original contributions on public health, preventive medicine, dietetics, materia medica, therapy, surgery, clinical observations, and practical medicoethical procedures. *Kitāb al-Malikī* was first rendered into Latin by Constantine Africanus (AD 1020–1087) under the title *Pantegni*, without giving credit to its original author. Al-Majūsī was fully recognized when the book was translated from Arabic into Latin by Stephen of Antioch in 1127. Since then, many editions in Latin and Arabic have appeared, and a facsimile edition was published in 1985 in two volumes.

Among the Arabic compendia on the theme of the healing arts in Islam, Majūsī’s *Kitāb al-Malikī* stands as one of the leading texts in its style, systematization, and precision. It was well read among students and practitioners alike. The judge and historian Ibn al-Qiftī praised Majūsī by saying that he “excelled in the study of medicine, [and] worked hard to comprehend its doctrines and laws from the original sources.”

Ibn al-Majūsī died in Shīrāz in AH 384/AD 994, leaving behind an essential document in the Arabic legacy to the history of the medical sciences in this golden age.

Ibn al-Nafīs

Albert Z. Iskandar

Ibn al-Nafīs, ‘Alā’ al-Dīn Abu’l-ḥasan ‘Alī Ibn Abī al-ḥazm al-Qurashī, was born in a village near Damascus (Syria). He studied medicine at the Great Nūrī Hospital (*al-Bīmāristān al-Nūrī*) in Damascus, founded by the Turkish ruler Nūr al-Dīn Maḥmūd Ibn Zankī (d. AD 1174). He chose to live, practice, and teach medicine in Egypt, where he eventually became a Chief of Physicians, and was also a personal doctor to the then-ruler al-Zāhir Baybars (r. ca. AD 1260–1277).

In addition to practicing medicine, he was a Shāfi ‘ī jurist, thoroughly educated in Islamic theology and jurisprudence at the Masrūriyya School (*Madrassa*) in Cairo. Hence, he is classed as a “jurist physician,” thus deviating from the

traditional image of the physician-philosopher Galen (d. ca. AD 200), which was so faithfully emulated by many medieval Arabic-speaking doctors, as for example ► [al-Rāzī](#) (Rhazes, d. AD 925) and Ibn Sīnā (Avicenna, d. AD 1037).

Ibn al-Nafis was a prolific author. Among his medical works is *Kitāb al-Shāmīl fī ‘l-ṣinā’ a al-Ṭibbiyya* (Comprehensive Book on the Art of Medicine). He jotted down preparatory notes for this voluminous book in 300 volumes, of which he managed to publish only 80. Its manuscripts, so far unpublished, are to be found in Cambridge University Library (Cambridge, England), the Bodleian Library (Oxford, England), and al-Muthaf al-‘Irāqī (Iraq). In 1960, three autographed manuscripts of this book were discovered in the Lane Medical Library (Stanford University). The first, referred to by Ibn al-Nafis himself as the 33rd *mujallad* (bound volume), is dated AH 641/AD 1243–1244. According to the author, the two other manuscripts are its 42nd and 43rd volumes.

It is of historical significance that Ibn al-Nafis, in *Kitāb al-Shāmīl*, divides the procedure to be followed by doctors in surgical operations into three stages: first, the “stage of presentation for clinical diagnosis”; second, the “operative stage”; and third, the “postoperative period,” during which the patient remains under the doctor’s supervision until full recovery is achieved.

Another important work is *Sharḥ Tashrīḥ Kitāb al-Qānūn fī ‘l-Ṭibb li-Ibn Sīnā* (Commentary on Anatomy in Avicenna’s Canon of Medicine). In it he gives the earliest known account of pulmonary circulation: “. . . This is the right cavity of the two cavities of the heart. When the blood in this cavity has become thin, it must be transferred into the left cavity, where the pneuma is generated. But there is no passage between these two cavities, the substance of the heart there being impermeable. It neither contains a visible passage, as some people have thought, nor does it contain an invisible passage which would permit the entry of blood, as Galen thought. The pores of the heart there are compact and the substance of the heart is thick. It must, therefore, be that when the blood has become thin, it is passed into the arterial vein

(pulmonary artery) to the lung, in order to be dispersed inside the substance of the lung, and to mix with the air. The finest parts of the blood are then strained, passing into the venous artery (pulmonary vein) reaching the left of the two cavities of the heart, after mixing with the air and becoming fit for the generation of pneuma. . .”

Ibn al-Nafīs’ discovery of pulmonary circulation antedates the accounts mentioned by Michael Servetus (AD 1553), Realdo Colombo (AD 1559), and Andrea Cesalpino (d. AD 1603). Andreas Vesalius (d. AD 1564), who does not mention blood circulation, refutes Galen in his statement: “. . . I do not see how even the smallest amount of blood could pass from the right ventricle to the left ventricle, through the interventricular septum. . .” We now say it was William Harvey (d. AD 1657) who, through experimentation which lasted almost 20 years, discovered the entire path of blood circulation.

Ibn al-Nafīs wrote a large textbook, *Al-Muhadhdhab fī ‘l-Kuḥl al-Mujarrab* (The Polished Book on Experimental Ophthalmology), divided into two sections: “On the Theory of Ophthalmology,” followed by detailed accounts of “Simple and Compounded Ophthalmic Drugs.”

A very popular and concise book was Ibn al-Nafīs’ *Mūjiz al-Qānūn fī ‘l-Ṭibb* (Abstract of Ibn Sīnā’s Canon of Medicine). It has been claimed – probably unfairly – that the tedious prolixity of Ibn Sīnā’s *Canon of Medicine*, together with the incomprehensibility of some of its statements, and Ibn al-Nafīs’ *Abstract of Avicenna’s Canon of Medicine*, with its undue brevity and popularity among Arabic-speaking students of medicine, led to the decline of late medieval medical education.

On the philosophy of religion, Ibn al-Nafīs wrote *Al-Risāla al-Kāmilīyya fī ‘l-Sīra al-Nabawīyya* (Missive on the Complete Prophetic Conduct), also known by the title *Fāḍil Ibn Nāṭiq*. It was written along the lines of Ibn Ṭufayl’s (d. AD 1185) *Ḥayy Ibn Yaqẓān*. In it, Ibn al-Nafīs imagines the generation – inside a cave on a deserted island – of a human being. The author guides the reader to the way in which this lone

human being would arrive at the discovery of science and philosophy, then the knowledge of prophecies, and particularly the *Sīra* (conduct) of the Prophet Muḥammad, and the legal doctrines of Islam.

In his old age, Ibn al-Nafīs bequeathed his own house, including an extensive private library, to the Qalāwūn Hospital, founded in AD 1284 by Sultan Qalāwūn (r. AD 1279–1290). Ibn al-Nafīs died in his 80s, a bachelor who devoted all his time to the practice of medicine on which he wrote several books. He died on 17th December 1288 (11th Dhu'l-Qa'dah 687).

Ibn al-Quff (al-Karakī)

Sami K. Hamarneh

Abū'l-Faraj ibn Ya'qūb ibn Ishāq Ibn al-Quff al-Karakī was born on the 22nd of August 1233, in the city of Karak (hence the name al-Karakī) in the district of Transjordan in larger Syria (*Bilād al-Shām*). The first and most intimate biography, by a friend of al-Karakī's family, was by Abū'l-Faraj's first teacher in the healing art – the prominent physician and historian of medicine Ibn Abī Uṣaybi'ah (d. 1270). The meeting between al-Karakī's family and Uṣaybi'ah took place in Ṣarkhad, Syria. As Uṣaybi'ah was the physician-counselor to the governor (*wālī*) of Ṣarkhad and the entire province, al-Karakī's family moved from Karak north to Ṣarkhad. The father was summoned by the governor to serve as a secretary to the Department of Welfare (*dīwān al-birr*). A very close friendship developed between the physician as a leading and resourceful practitioner, and Ya'qūb al-Karakī as an able secretary, adviser, historian, linguist, and man of letters.

At that time, the son Abū'l Faraj was 11 or 12 years of age, a bright fellow who had acquired the basics in education in Karak. The father asked the physician if he would teach his son the healing art, and Uṣaybi'ah willingly accepted the challenge. He soon taught him the basics of the field: the theory and practical aspects of medicine, methods of treatment, and the identification of causes and symptoms of diseases.

The major texts which were studied included some of the writings of Hippocrates (known as the Hippocratic *corpus*, such as the *Aphorisms and Prognoses*) and some of the medically important catechisms, such as *Al-Masā'il* by ► [Hunayn ibn Ishāq](#) (809–873), and the major writings of ► [al-Rāzī](#) (Latin Rhazes, 865–925), particularly the clinical and therapeutic texts.

After the fall of the Ṣarkhad province into the hands of the Ayyūbid King, al-Ṣāliḥ Najm al-Dīn (1245–1249), al-Karakī's family moved to Damascus (the Syrian capital of the Ayyūbids)

where the father was promoted to a higher position. The son continued his study under some of the most illustrious physicians at the time. Damascus had great hospitals, including the hospital located in the Citadel for the Royal family, civil servants, and army personnel. There Ibn al-Quff had his training to become a physician.

This medieval period had witnessed great cultural, political, and technoscientific changes. There was the fall of the prestigious Fātimid (Shī'ite) dynasty in Cairo, and the rise of the Ayyūbid (Sunnite) dynasty in Cairo and Damascus under the leadership of Sultān Ṣalāḥ al-Dīn (Saladin, r. 1171–1193) and his successors. There was also the rise of the *Bahri Mamluks* (slave sultans 1250–1381). However, the true founder of the “Slave” dynasty was Sultān al-Zahir Baybars (d. 1277), who was first purchased to serve in the Ayyūbid army and then became their ruler. During this time, the healing arts reached new heights.

Having had excellent training and having become a worthy practitioner-surgeon, Ibn al-Quff was summoned in about 1262 (at the age of 29) to be the physician-surgeon in 'Ajlūn, his home country in Transjordan. There he served the profession for a decade, at the end of which he published his first medical encyclopedia *Al-Shāfī al-Ṭibb* (The Comprehensive of the Healing Arts), completed in early 1272. It is composed of 12 treatises encompassing the entire medical field. It was a significant contribution to the field at the time and contained many timely observations and innovations.

From 'Ajlūn, al-Karakī was summoned to the Syrian capital, Damascus. There he served at its Citadel and hospital from 1272 until his untimely death in early July 1286 at the age of 52. We know that many medical students came to hear his lectures and listen to his eloquence. He also continued to fulfill his duty in caring for the sick and the wounded and continued his research and publications. Among these are two commentaries: one on the Hippocratic *Aphorisms*, entitled *al-Uṣūl*, edited in Cairo, and the other a commentary on the generalities of the *Qānūn* of Ibn Sīnā (d. 1037). The last *Sharh* was complete about 1274.

His other work is *Jamī' al-Gharāḍ*, on preventive medicine and the preservation of health in 60 chapters, completed about 1275. It is extant in several manuscripts. This is possibly the finest work of its kind in medieval times, and it needs translation into English for wider audiences.

Al-Karakī's best and most renowned manual is *al-'Umdah* on surgery. It was published in Hyderabad, India, in 1356 AH/1937 and ranks second after *al-Taṣrīf* (The Thirtieth Treatise) by al-Zahrāwī (Abulcasis, ca. 939–1013).

Only recently have al-Karakī's literary contributions begun to draw wider recognition. His writings should place him among the greatest physician-surgeons and public health experts during the Arab-Islamic Golden Age.

Ibn al-Raqqām

Julio Samsó

Muḥammad ibn al-Raqqām al-Andalusī (d. 1315) was an Andalusian astronomer, mathematician, and physician. He was probably born in Murcia and left the city when it was conquered by ► [Alfonso X](#) in 1266. He lived in Bejaia (Algeria), Tunis and, after 1280, accepted the invitation of Muḥammad II (1273–1302) and established himself in Naṣrid Granada where he taught mathematics and astronomy (as well as medicine and law). Among his students in astronomy we find king Naṣr (1309–1314). His son, Ibrāhīm ibn Muḥammad ibn al-Raqqām, was an astrolabe maker: one of his instruments (made in Guadix in 1320) is still preserved in Madrid.

Among his extant works we should mention his *Risāla fī ‘Ilm al-Zilāl* (Treatise on the Science of Shadows) as well as two sets of astronomical tables (*zīj*es), the first of which was probably compiled in Bejaia in 1280–1281, while the second was made in Tunis and later adapted to the coordinates of Granada. His book on *Shadows* is a brilliant treatise on Gnomonics where Ibn al-Raqqām explains how to build all kinds of sundials (among which we find a portable sundial which includes a compass) using projections on a plane which, ultimately, derive from Ptolemy’s *Analemma*. The first of his *zīj*es, entitled *al-Zīj al-Shāmīl fī Tahdhīb al-Kāmil* (A General Set of Astronomical Tables in which [Ibn al-Hā’im’s] Kāmil ► [Zīj](#) is Corrected), follows narrowly the theoretical contents of Ibn al-Hā’im’s *al-Zīj al-Kāmil fī l-Ta’ālīm* to which Ibn al-Raqqām adds

the numerical tables which had been lost in the manuscript of Ibn al-Hā’im’s work. His second *zīj al-Zīj al-Qawīm fī Funūn al-Ta’dīl wa-l-Taqwīm* (The Solid Handbook to Calculate Equations and Planetary Positions) is a summary and adaptation of the first one to the coordinates of Tunis and Granada. Both works bear witness to the diffusion of Ibn al-Zarqāllu’s astronomical ideas in the Maghreb and Andalusia.

Ibn al-Shāṭir

David A. King
Frankfurt University, Frankfurt am Main,
Germany

Ibn al-Shāṭir, ‘Alā’ al-Dīn ‘Alī ibn Ibrāhīm, was born in Damascus ca. 1305. He was the most distinguished Muslim astronomer of the fourteenth century. Although he was the head *muwaqqit* at the Umayyad mosque in Damascus,

responsible for the regulation of the astronomically defined times of prayer, his works on astronomical timekeeping are considerably less significant than those of his colleague al-Khalīlī. On the other hand, Ibn al-Shāṭir made substantial advances in the design of astronomical instruments. Nevertheless, his most significant contribution to astronomy was his planetary theory.

In his planetary models Ibn al-Shāṭir incorporated various ingenious modifications of those of Ptolemy. Also, with the reservation that they are geocentric, his models are the same as those of Copernicus. Ibn al-Shāṭir's planetary theory was investigated for the first time in the 1950s, and the discovery that his models were mathematically identical to those of Copernicus raised the very interesting question of a possible transmission of his planetary theory to Europe. This question has since been the subject of a number of investigations, but research on the astronomy of Ibn al-Shāṭir and his sources, let alone on the later influence of his planetary theory in the Islamic world or Europe, is still at a preliminary stage.

Ibn al-Shāṭir appears to have begun his work on planetary astronomy by preparing a *zīj*, an astronomical handbook with tables. This work, which was based on strictly Ptolemaic planetary theory, has not survived. In a later treatise entitled *Ta'liq al-arṣād* (Comments on Observations), he described the observations and procedures with which he had constructed his new planetary models and derived new parameters. No copy of this treatise is known to exist in the manuscript sources. Later, in *Nihāyat al-su' l fī taṣḥīḥ al-uṣūl* (A Final Inquiry Concerning the Rectification of Planetary Theory), Ibn al-Shāṭir presented the reasoning behind his new planetary models. This work has survived. Finally, Ibn al-Shāṭir's *al-Zīj al-jadīd* (The New Astronomical Handbook), extant in several manuscript copies, contains a new set of planetary tables based on his new theory and parameters.

Several works by the scholars of the mid-thirteenth century observatory at Maragha are mentioned in Ibn al-Shāṭir's introduction to this treatise, and it is clear that these were the main sources of inspiration for his own non-Ptolemaic planetary models.

The essence of Ibn al-Shāṭir's planetary theory is the apparent removal of the eccentric deferent and equant of the Ptolemaic models, with secondary epicycles used instead. The motivation for this was at first sight aesthetic rather than scientific, but his major work on observations is not available to us, so this is not really verifiable. In any case, the ultimate object was to produce a planetary theory composed of uniform motions in circular orbits rather than to improve the bases of practical astronomy. In the case of the sun, no apparent advantage was gained by the additional epicycle. In the case of the moon, the new configuration to some extent corrected the major defect of the Ptolemaic lunar theory, since it considerably reduced the variation of the lunar distance. In the case of the planets, the relative sizes of the primary and secondary epicycles were chosen so that the models were mathematically equivalent to those of Ptolemy.

Ibn al-Shāṭir also compiled a set of tables displaying the values of certain spherical astronomical functions relating to the times of prayer. The latitude used for these tables was 34° , corresponding to an unspecified locality just north of Damascus. These tables display such functions as the duration of morning and evening twilight and the time of the afternoon prayer, as well as standard spherical astronomical functions.

Ibn al-Shāṭir designed and constructed a magnificent horizontal sundial that was erected on the northern minaret of the Umayyad Mosque in Damascus. The instrument now on the minaret is an exact copy made in the late nineteenth century. Fragments of the original instrument are preserved in the garden of the National Museum, Damascus. Ibn al-Shāṭir's sundial, made of marble and a monumental 2×1 m in size, bore a complex system of curves engraved on the marble which enabled the *muwaqqit* to read the time of day in equinoctial hours since sunrise or before sunset or with respect to either midday or the time of the afternoon prayer, as well as with respect to daybreak and nightfall. The gnomon is aligned towards the celestial pole, a development in gnomonics usually ascribed to European astronomers.

A much smaller sundial forms part of a compendium made by Ibn al-Shāṭir, now preserved in Aleppo. It is contained in a box called *Ṣandūq al-yawāqīt* (jewel box), measuring $12 \times 12 \times 3$ cm. It could be used to find the times (*al-mawāqīt*) of the midday and afternoon prayers, as well as to establish the local meridian and the direction of Mecca.

Ibn al-Shāṭir wrote on the ordinary planispheric astrolabe and designed an astrolabe that he called *al-āla al-jāmiʿa* (the universal instrument). He also wrote on the two most commonly used quadrants, the astrolabic and the trigonometric varieties. Two special quadrants which he designed were modifications of the simpler and ultimately more useful sine quadrant. One astrolabe and one universal instrument actually made by Ibn al-Shāṭir survive.

A contemporary historian reported that he visited Ibn al-Shāṭir in 1343 and inspected an “astrolabe” that the latter had constructed. His account is difficult to understand, but it appears that the instrument was shaped like an arch, measured three-quarters of a cubit in length, and was fixed perpendicular to a wall. Part of the instrument rotated once in 24 h and somehow displayed both the equinoctial and the seasonal hours. The driving mechanism was not visible and probably was built into the wall. Apart from this obscure reference, we have no contemporary record of any continuation of the sophisticated tradition of mechanical devices that flourished in Syria some 200 years before his time.

Ibn al-Shāṭir died in Damascus ca. 1375. Later astronomers in Damascus and Cairo, none of whom appears to have been particularly interested in his non-Ptolemaic models, prepared commentaries on, and new versions of, his *zīj*. In its original form and in various recensions, this work was used in both cities for several centuries. His principal treatises on instruments remained popular for several centuries in Syria, Egypt, and Turkey, the three centers of astronomical time-keeping in the Islamic world. Thus, his influence in later Islamic astronomy was widespread but, as far as we can tell, unfruitful. On the other hand, the reappearance of his planetary models in the writings of Copernicus strongly suggests the

possibility of the transmission of some details of these models beyond the frontiers of Islam.

Ibn al-Yāsamīn

Ahmed Djebbar

The name of this mathematician is Abū Muḥammad ‘Abdallāh ibn Muḥammad ibn Hajjāj al-Adrīnī, more commonly known as Ibn al-Yāsamīn. As his name indicates, he was originally from a Berber tribe from the Maghreb (North Africa), and, according to Ibn Sa‘īd, he was black like his mother. We know nothing about the exact date of his birth, but can reasonably place it in the second half of the twelfth century. We also know nothing specific about his place of birth, which could have been in the Andalus (Spain) or the Maghreb. But since some historians have given him the surname al-Ishbīlī, he may have been born or grown up in Seville. In any case, Ibn Sa‘īd states that his formative education occurred in Seville.

This education was not restricted to mathematics, since we know he also became famous

in the fields of law and literature, particularly in the Andalusian poetry of the Muwashshahāt. That being said, however, we know nothing of the context in which he received this rich education nor of his teachers. The only information we have is from Ibn al-Yāsamīn himself about one of his professors, Abū ‘Abdallāh Muḥammad ibn Qāsim al-Shalūbīn, who taught him algebra and the science of calculation.

We also do not know exactly when Ibn al-Yāsamīn began to publish his mathematical writings. Ibn al-Abbār tells us only that Ibn al-Yāsamīn’s famous algebraic poem was drafted in Seville and that, in 1190 also in Seville, he was using it in his teaching.

Concomitant with his mathematical activities was Ibn al-Yāsamīn’s dedication to poetry, and according to Ibn Sa‘īd, some of his poems had even been set to music and sung at this time. It may have been his literary success which led to his frequenting the court of the third Almohad caliph Abū Yūsuf Ya‘qūb (1184–1199) and of his successor Muḥammad al-Nāṣir (1199–1213). These frequent court visits and the fame of his literary and mathematical publications probably gained Ibn al-Yāsamīn some enemies. Also some of his contemporaries accused him of leading a dissolute life. But none of these can be seen as the cause of his assassination in 1204 in Marrakesh.

The Mathematical Writings of Ibn al-Yāsamīn

The best-known work of Ibn al-Yāsamīn is a poem of 53 verses in rajaz meter entitled *al-Urjūza al-yāsmīnīyya fī al-jabr wa ‘l-muqābala* (Poem on Algebra and Restoration). In it the author defines the algebra known in his time – number, root, and sequence, then the six canonical equations of ► [al-Khwārizmī](#) with the processes of solving them, and finally, the operations of algebra – the restoration, comparison, multiplication, and division of monomials.

This poem has been widely read throughout the centuries both within the Maghreb and beyond. Thus, there are many commentaries on

it by other famous mathematicians such as ► [Ibn Qunfudh](#) (d. 1407) and ► [al-Qalaṣādī](#) (d. 1486) in the Maghreb, ► [Ibn al-Hā'im](#) (d. 1423) and Sibṭ al-Mārādīnī (d. 1501) in Egypt and elsewhere.

For a long time, the contribution of Ibn al-Yāsamīn to mathematics was known only through his *Urjūza* in algebra. It is quite possible, moreover, that it was the success of this poem which led him to write a second one on irrational quadratic numbers and maybe a third on the method of false position. But the distribution of these last two poems was relatively modest, compared to that of the first one, and aside from the rare copies that exist, we have not yet found any explicit reference to the contents of the two other poems in any works on calculation written after the twelfth century.

The same situation exists for Ibn al-Yāsamīn's fourth written work on mathematics, entitled *Talqīḥ al-afkār bi rushūm Ḥurūf al-ghubār* (Fertilization of Thoughts with the Help of Dust Letters [Hindu Numerals]). This work is much more important than his poems, as much in quantity as in quality. Indeed, it is a book of 200 folios which contains classic chapters on the science of calculation and on geometry. Among the works of the Muslim West which have come down to us, it is the only one which consolidates these two disciplines. Its importance is also due the nature of its materials and its mathematical tools which make it an original book and also one which is totally representative of this period of transition in which three mathematical traditions were juxtaposed – of the East, the Andalus, and the Maghreb – before they became blended in the same mold.

For example, the following elements contribute both to the originality of his work and to its being anchored in the great Arab mathematical tradition of the ninth to eleventh centuries:

In arithmetic, contrary to the Maghrebian tradition which prevailed from the fourteenth century on, Ibn al-Yāsamīn treats multiplication and division first, before addition and subtraction. This approach, which can be found again later in the work of Ibn al-Zakariyā' al-Gharnāfi, seems to be based on Andalusian mathematical practice.

For fractions, the remarks and suggestions of Ibn al-Yāsamīn concerning the reading of certain expressions demonstrate that the symbolism of fractions had not been established definitively in his time. This was not the case, it appears, for the symbolism of equations which had been established relatively early, since there is no difference between the symbols used in the *Talqīḥ al-afkār* of Ibn al-Yāsamīn and those used in the *Bughyat at-tullāb* (The Hope of Students) of Ibn Ghāzī al-Miknāsī (d. 1513).

As for the presence of geometry in a work on the science of calculation, this is not exceptional in regard to the Arab mathematical tradition, viewed in its entirety, in so far as similar chapters (i.e., chapters which deal with problems in metric geometry) had already been inserted in works edited in the East, such as the *Takmila fi l-hisāb* (Complement to Calculus) of 'Abd al-Qāhir al-Baghdādī or the *Kitāb al-Kāfi* (The Sufficient Book) by ► [al-Karajī](#).

In spite of what we have noted about the contents of *Talqīḥ al-afkār*, there has not been any explicit reference to the book in Maghrebian mathematical writing. There could be at least two possible explanations for this. First, a break in the tradition whose cause is to be found outside the scientific milieu of that time. This hypothesis is not implausible if one takes into account the personality of Ibn al-Yāsamīn and his controversial behavior and also his close ties to Almohad power.

The second reason, which is also plausible and which can be added to the first, can be found in mathematical practice after Ibn al-Yāsamīn, a practice which bore the strong imprint of mathematicians from Marrakesh, like Ibn Mun'im (d. 1228), al-Qāḍī al-Sharīf (d. 1282–1283), and ► [Ibn al-Bannā'](#) (d. 1321). We have observed this same phenomenon of the absorption of a mathematical tradition first in the East with the first written Arab arithmetical works from the ninth century and, in particular, with the work of ► [al-Khwārizmī](#), and then in the Andalus with writings of the tenth century, like those of ► [al-Majrīṭī](#) and his pupils.

Ibn Al-Zarqāllu

Emilia Calvo

Ibn al-Zarqāllu, Abū Ishāq Ibrāhīm ibn Yaḥyā al-Naqqāsh, sometimes known as Azarquiel, was born in the first quarter of the eleventh century to a family of artisans. He entered the service of the *qāḍī* (judge) Ṣāʿid of Toledo first as an artisan, and after as the director of a group which carried out astronomical observations. Ibn al-Zarqāllu lived in Toledo until ca. AD 1078, when he moved to Cordoba where he composed his last works under the patronage of the king of Sevilla al-Muʿtamid ► [ibn ʿAbbād](#) and where he died in AD 1100. His work exerted

considerable influence on later authors such as ► [Ibn al-Kammād](#), Abū'l-ḥasan ʿAlī Ibn al-Bannā, Abraham ibn ʿEzra, ► [Ibn al-Hāʾim](#), Ibn Ishāq, and Ibn Bāṣo.

Ibn al-Zarqāllu's works are basically astronomical, although an astrological treatise by him is also extant. Other works of Ibn al-Zarqāllu are described below:

The *Almanac* is a reelaboration by Ibn al-Zarqāllu of the work of an unknown author called Awmātiyūs. It allows the determination of planetary longitudes, without computation, by combining Ptolemaic parameters with the Babylonian doctrine of the goal-years. The goal-years consisted of cycles peculiar to each planet. These cycles included an entire number of solar years which, in turn, comprised an exact number of synodic and zodiacal revolutions. These cycles were known by the Babylonian astronomers, and they are also found in Ptolemy's *Almagest*. The advantage of these cycles for astronomers is that the positions of the planets can be calculated for a complete cycle which will be repeated, so these positions will always be the same for a given date within the cycle.

Treatise on the Motion of the Fixed Stars is preserved in a Hebrew translation. It is probably the most complete medieval text on the trepidation theory. Trepidation consists of a back-and-forth vibration within fixed limits, which is supposed to account for the variation in velocity of the slow eastward motion observed in the fixed stars. The treatise proposed three different geometrical models to demonstrate this theory.

Fīsanat al-šams (On the Solar Year) was probably written between AD 1075 and 1080 and based on 25 years of solar observations. Here Ibn al-Zarqāllu established the proper motion of the solar apogee to be of 1° in 279 Julian years. The text is lost but it can be reconstructed from the works of later astronomers like Ibn al-Kammād, Ibn al-Hāʾim, Ibn Ishāq, ► [Ibn al-Raqqām](#) and ► [Ibn al-Bannā](#).

Risālat al-ṣafīḥa al-zarqāliyya (Treatise on the Zarqāliyya Plate) and *Risālat al-ṣafīḥa al-shakkāziyya* (Treatise on the Shakkāziyya Plate) are two treatises on the use of a universal astrolabe called *Ṣafīḥa* (plate). There is an Alphonsine translation in the *Libros del Saber de Astronomia* of the treatise on the use of the *Ṣafīḥa zarqāliyya*.

This instrument offers the possibility of making calculations for any given latitude by means of only one plate.

Kitāb al-ʿamal bi'l-ṣafīḥa al-zījīyya (Treatise on the Plate for the Seven Planets) describes the equatorium, an instrument consisting of the representation, drawn to scale, of a planetary model, which is used to determine the position of a planet at a given moment. Both his treatise on its construction and his treatise on its use are extant.

He also took an active part in the elaboration of the *Toledan Tables* which seem to have been the result of the work of a group of astronomers directed by the *qāḍī* Ṣāʿid.

Finally, he was probably the author of a treatise on the construction of the armillary sphere, translated or adapted by Ishāq ibn Sīd, which was incorporated into the Alphonsine *Libro de las Armellas*.

Ibn Baṭṭūṭa

Bilal Ahmad

Ibn Baṭṭūṭa (1304–1369) was the greatest Muslim traveler of his time. He was born in Tangier to a well-educated Moroccan family that produced many judges. After receiving basic education in his home town, at age 21 he headed toward Mecca both to make a pilgrimage and to study under some notable Muslim scholars in Egypt, Syria, and Hejaz. After reaching Egypt via Tunis and Tripoli, he decided to become a traveler to gain firsthand knowledge about as many parts of the world as possible. Ibn Baṭṭūṭa's fascination for travel took him to Syria, Iraq, southern Iran, and Azerbaijan. He then decided to spend the next 3 years (1327–1330) in the holy towns of Mecca and Medina in Hejaz. Ibn Baṭṭūṭa's next expedition (1330–1332) started from the seaport of Jidda. He sailed across the Red Sea to Yemen, traveled across Yemen by land, and from Aden he sailed along the coast to various trading ports of East Africa. On his way back, he turned his boat to the Persian Gulf area and concluded this trip by another pilgrimage to Mecca.

Ibn Baṭṭūṭa's travels were supported by the contributions of the rulers, governors, and other prominent residents of the places that he visited. After hearing of the benevolence of Muḥammad bin Tughlaq – the ruler of Delhi, India – Ibn Baṭṭūṭa decided to go to India. This time he adopted a very unusual route: by moving northward, he first passed through Egypt and Syria; he

then traveled extensively in Anatolia (Asia Minor) and the territories of the Golden Horde where he was well received by the local sultans and other prominent people. Ibn Baṭṭūṭa's *Riḥlah* (Book of Travels) provides a clear and lucid picture of Constantinople, Saray (the capital of the Khan of the Golden Horde), and other Sultanates. After crossing the Steppes with a caravan, Ibn Baṭṭūṭa passed through the towns of Bukhara, Samarkand, Balkh, and Herat. He then crossed the Hindu Kush Mountains and visited many important towns and cities in the Indus Valley – particularly Sukkur, Multan, and Lahore – before he finally reached Delhi. Sultan Muḥammad bin Tughlaq received him with respect and presents. The Sultan also appointed him the chief justice of Delhi. Ibn Baṭṭūṭa enjoyed the patronage of the Sultan for several years.

In 1342, he appointed Ibn Baṭṭūṭa the ambassador to China. After his ship wrecked near Calicut on the Malabar Coast of India, he decided to go to the Maldives where he married into the royal family. In the following years, Ibn Baṭṭūṭa visited Sri Lanka (Ceylon), supported the Sultan of the Maldives in a war, went again to the Maldives, and visited Bengal, Assam, and Sumatra. The Sultan of Sumatra provided him with a new ship to go to China. He arrived at the Chinese port of Zaytun and reached Beijing via the inland waterways. On his return journey, he eventually reached Mecca via Sumatra, Calicut, the Persian Gulf, Baghdad, Syria, and Egypt. Ibn Baṭṭūṭa's narrative for this entire journey is sketchy and some scholars doubt that he ever reached Beijing.

In April to May of 1349, Ibn Baṭṭūṭa embarked for his home from Alexandria via Tunis, Sardinia, and Algeria. He eventually reached Fez (Morocco), from where he went to the Kingdom of Granada, in Spain. His next destination was western Sudan. After traveling across the Sahara, he visited the Empire of Mali and returned to retire in Fez.

Ibn Baṭṭūṭa was an outstanding adventurer. His education and experience earned him numerous honors and awards, including the position of judge in many parts of the Muslim world. After

his retirement, he again held the office of *qāḍī* (judge) in a Moroccan town and dictated his recollections to Ibn Juzayy – a royal poet. Ibn Baṭṭūṭa's *Riḥlah* is a valuable document for understanding the ways of life in the fourteenth-century Muslim world.

Ibn Buṭlān

Roger Arnaldez

Abū'l-ḥasan al-Mukhtār ibn 'Abdūn ibn Sa'dūn Ibn Buṭlān was a physician, philosopher, and Christian theologian from Baghdad (eleventh century). He had for a teacher a Nestorian priest, Abū'l-Faraj ibn al-Ṭayyib, a commentator on Aristotle, Hippocrates, and Galen, who was interested in botany and wrote on the humors, wine, and natural qualities. Teaching at the hospital founded in Baghdad by 'Aḍud al-Dawla, he directed his pupil in reading and the use of several medical works. He taught him so well that later, Ibn Buṭlān, in a controversy with the physician ► [Ibn Riḍwān](#), maintained that one could understand the basic precepts of medicine by simply reading books.

On the subject of the *al-Masāʾil fiʾl-Ṭibb fiʾl-Mutaʿāllimīn* (Questions on Medicine for Students) by ► [Ḥunayn ibn Ishāq](#), he believed that Ibn Riḍwān, who had refuted it, had not understood it at all, “because he didn’t study it under the direction of masters in this art.” That is why, in spite of his great knowledge of the works of the Ancients, he refused to conform blindly and to the letter. Also he asked why clear-sighted doctors had lost the habit of caring for certain maladies, as the Ancients had done, with warm medicines, and preferred to use cold ones. It seems also that Ibn Buṭlān was instructed in the practice of medicine by Abūʾl-ḥasan Thābit ibn Ibrāhīm al-ḥarrānī, about whom many praises were said.

Ibn Buṭlān left Baghdad, crossed Syria, and arrived in Egypt, where he undertook several polemics with Ibn Riḍwān. These covered diverse subjects, touching in particular the philosophical questions and ideas of Aristotle concerning place, movement, and the soul on which Ibn Riḍwān had commented before. He returned to Constantinople, where he arrived in 446/1054, at the time of the schism which would eventually separate the Greek from the Latin church. The patriarch Michel Cérulaire asked him to edit a treatise on the Eucharist and the use of bread without leavening. That was also the year when a terrible epidemic of the plague broke out in the capital of the Byzantine Empire. Ibn Buṭlān kept a diary and cited the names of several savants who had succumbed to it. After this he went to Antioch where he directed the establishment of a hospital. Eventually he retired from traveling, and died in 460/1068.

His work is very diverse, covering theology, philosophy, logic, and medicine. His interpretation of the work of the Ancients is original and animated by a critical spirit. He relied on logic and the grammar of languages, and attempted to explain apparent opposition by showing that they had very different points of view. Thus Aristotle studied organic forces relative to their nature, while Galen did so relative to their perceptible action in the organs which were their instruments. Aristotle divided the organs according to their

physical constitution, Galen in relation to the illnesses which affected them. In the same way, with regard to the “egg yolk” color of bile, Ibn Buṭlān tended to agree with Galen who explained it by the predominant action of heat, which rends the bile hotter and lighter. On the other hand, Ḥunayn ibn Ishāq explained it as the result of a mixture of bile and phlegm. These differences can be explained by the ambiguity of the term *muḥḥ*, which signifies at the same time both the egg yolk alone and the entire interior of the egg, both the yellow and the white.

Ibn al-Qifṭī retained for us a list of the problems that Ibn Buṭlān posed. For example, he wondered about the chemical nature of the force of physical attraction between lovers. In the field of physiology, he questioned why it is that when men dream they are urinating, they wake themselves up without urinating in their beds, while when they dream of a sexual encounter, there is an emission of sperm. He wondered why this was so, when you consider how much easier it is to urinate than to ejaculate when one is awake.

Ibn Buṭlān’s most important medical work is the *Taqwīn al-ṣiḥḥa* (Strengthening of Health), a treatise on hygiene dedicated to general questions on the four elements, the humors, and the temperaments. The author studied the nature and value of nutrition, as well as the influence of the environment, water, climate, and housing on health. The originality of the work lies in its form: it is presented in small tableaux. It was translated into Latin and German. Another noteworthy work is *Daʿat al-Aṭibbā* (The Physician’s Banquet), on the subject of medical ethics, which included a satire on charlatans and ignorant physicians. There is also a treatise on the maladies caused by food, with recommended remedies used by monks. Finally, there is a treatise devoted to a discussion of whether a chicken is hotter than a smaller bird.

Ibn Ḥawqal

Emilia Calvo

Ibn Ḥawqal al-Nasibī Abū'l-Qāsim Muḥammad ibn 'Alī was born in Nisibis (now Nusaybin, Turkey) in the second half of the tenth century. He worked as a merchant and traveled, beginning in AD 943, through the Muslim world, visiting the Maghreb and Andalusia between 947 and 951; Egypt, Armenia, and Azerbaijan around AD 955; Iraq, Persia, Transoxiana, and Khwarazm between 961 and 969. In AD 973, he was in Sicily.

Ibn Ḥawqal is the author of a book on geography entitled *Kitāb al-masālik wa'l-mamālik* (Book on the Routes and Kingdoms), also known as *Kitāb Ṣūrat al-'arḍ*, which belongs to the category of the so-called *Atlas of Islam*. It consists of a description of the Islamic countries, although some non-Islamic regions of Sudan, Turkey, Nubia, and Sicily are also described.

Ibn Ḥawqal based his work on al-Iṣṭakhrī's book and incorporated new material from his travels which led to three successive revisions of his *Kitāb al-masālik*: the first one in AD 967, dedicated to Sayf al-Dawla; the second ca. AD 977, and the third ca. 988. The final result was a book whose descriptive part surpassed the works of earlier authors.

From the contents of his work, his sympathy with the Fāṭimid movement can be deduced. He showed a certain interest toward Fāṭimid politics, although he cannot be considered a Fāṭimid *dā'ī* (propagandist). He also gives economic information. His interests are focused not on rare or precious goods but on basic agricultural and artisanal products.

Ibn Ḥawqal's *Kitāb al-masālik* influenced the work of later geographers such as Abū'l-Fidā. He is also the author of a book on Sicily which is not preserved.

Ibn Hubal

E. Ruth Harvey

Muhadhdhib al-Dīn Abū'l-ḥasan 'Alī ibn Aḥmad ibn 'Āli ibn Hubal al-Baghdādī was a famous physician, medical authority, and accomplished poet. Born in Baghdad in 1121 (AH 515), he migrated to Khilat (modern Ahlat, on the shore of Lake Van, Turkey), and became very prosperous in the service of the local ruler. He later moved to Mardin to serve another lord, and died at Mosul (in modern Iraq) in 1213 (AH 610). His chief work, *Kitāb al-Mukhtār fī al-Ṭibb* (The Choice Book of Medicine), was written in about 1165. It resembles the medical encyclopedias of Ibn Sīnā and ► [al-Rāzī](#) in that it is a compendium of Galenic medical knowledge, supplemented by personal clinical practice. *The Choice Book* is divided into three main parts, comprising anatomy and general principles, a pharmacopoeia, and a list of maladies arranged according to the affected organs, running from head to foot. Although this large book does not seem to have been translated into Latin during the Middle Ages, the number, diffusion, and varying ages of the manuscript copies attest to its popularity. No copy appears to survive of Ibn Hubal's *Kitāb al-Ṭibb al-Jamālī* (Book of Medicine for Jamal al-Din al-Wazir). A short work on logic, *al-Ārā' wa'l-mushāwarāt*, in manuscript in Paris (B.N. MS 2348) is ascribed to him.

The manuscripts of *The Choice Book* in Leiden, Paris, Cairo, and India are listed in Brockelmann; there are also several copies in Turkey, and fragmentary ones in Princeton and the British Library in London (the London text starts with the diseases of the brain). The whole Arabic text was edited in Hyderabad 1943–1944, but Albert Dietrich maintains that a proper critical edition is still badly needed. Two chapters of Ibn Hubal's medical encyclopedia were

published from the Leyden manuscript with an accompanying French translation; they describe the causes, symptoms, and treatment of stones in the kidneys and bladder. Ibn Hubal employs the usual medieval medical terminology derived from earlier Greek physicians: four fluids, or humors, within the body (blood, phlegm, choler (yellow bile), and melancholy (black bile)) are held to constitute in their balance and proportions the essential foundations of good health; pain and disease reveal an evil condition or imbalance among the fluids. Most remedies and treatments consist of trying to correct the malfunctioning fluid through diet, bleeding, or alteration of the patient's physical surroundings. In spite of what we might today consider the erroneous basis of his theoretical approach, Ibn Hubal shows an impressive concern for personal observations and clearly relies on extensive clinical practice. In discussing stones, for instance, he attributes the condition to excessive bodily heat which causes phlegm, a "thick fluid," to form deposits in the kidneys and bladder. He prescribes medicines such as horseradish, ginger, and chicken soup to break up the stones or cause them to be passed. He also cites his own personal experience of a more desperate remedy which he witnessed: a surgical operation to remove a bladder stone from a boy. He cites al-Rāzī and Rufus of Ephesus, but conveys the impression of a knowledgeable practical physician, mindful of the agonizing pain caused by the condition he is discussing.

Ibn Ishāq Al-Tūnisī

Julio Samsó

Abū-l-ʿAbbās Aḥmad ibn ʿAlī ibn Ishāq al-Tamīmī al-Tūnisī was a Tunisian astronomer of the early thirteenth century. He compiled an impressive astronomical handbook with tables (*zīj*) a manuscript of which (copied ca. 1400) was discovered by David A. King. It contains an important set of tables (completed ca. 1218) which mark the starting point of a Maghribian (North Africa) astronomical school. Parts of these tables seem original and are based, according to the famous historian ► [Ibn Khaldūn](#), on observations made by a Sicilian Jew. The rest is a miscellaneous collection of materials which derive from Andalusian sources, many of which seem lost, by ► [Ibn al-Zarqāllu](#) (d. 1100), Ibn Muʿādh al-Jayyānī (d. 1093), ► [Ibn al-Kammād](#) (fl. ca. 1125), ► [Ibn al-Hāʾim](#) (fl. ca. 1204) as well as others. The canons (instructions for the use of the numerical tables) were not written by Ibn Ishāq but by some later author who also used materials derived from the aforementioned Andalusian *zīj*es. Ibn Ishāq's *zīj* is, therefore, a first rate new source for the study of both Andalusian and Maghribian astronomy.

Ibn Juljul

Emilia Calvo

Ibn Juljul al-Andalusī, Sulaymān ibn Ḥasan, was born in Córdoba in AD 943 and died ca. 994. He studied medicine with a group of Hellenists presided over by Ḥasdāy ibn Shaprūt, a Jewish physician and vizier of the Caliph ʿAbd al-Raḥmān III, and later became the personal physician of Caliph Hishām II (976–1009).

Ibn Juljul is the author of *Ṭabaqāt al-aṭibbāʾ wa ʿl-ḥukamāʾ* (Generations of Physicians and Wise Men), the oldest extant summary in Arabic on the history of medicine (it was finished in AD 987), after Ishāq ibn Ḥunayn's *Taʾrīḥ al-aṭibbāʾ* (History of the Physicians). It contains 57 biographies grouped into nine generations. Thirty-one of them concern Asian authors, and the rest refer to African and Andalusian scholars.

Ibn Juljul used Eastern sources (Hippocrates, Galen, Dioscorides) and Western ones (Orosius, Isidore) and established the chronological limits of the Latin influence on medicine in Andalusia. The work has chronological errors but provides interesting information about the oldest translations into Arabic, in the time of the Caliph ʿUmar II (AD 717–719).

Other works of Ibn Juljul are *Tafsīr asmāʾ al-adwiya al-mufrada min kitāb Diyusqūridūs* (Explanation of the Names of the Simple Drugs from Dioscorides' Book), written in 982, from which only a fragment is preserved, containing the transcription of the Greek names of 317 simple medicines, their translation into Arabic and their identification; *Maqāla fī dhikr al-adwiya al-mufrada lam yadhkurha Diyusqūridūs* (Treatise on the Simples not Mentioned by Dioscorides), which includes 62 simple medicines not mentioned in Dioscorides' *Materia Medica*; *Maqāla*

fī adwiyat al-tiryāq describing the components of the theriac; and *Risālat al-tabyīn fī-mā ghalāṭa fīhi ba'd al-mutaṭabbibīn* (Treatise on the Explanation of the Errors of Some Physicians).

Ibn Jumay'

Hartmut Fahndrich

A contemporary of the great Jewish doctor and philosopher ► [Moses Maimonides](#), Ibn Jumay', was one of the physicians in the service of Ṣalāh ad-Dīn. He was born of a Jewish family in Fustat (Egypt) and studied with another physician of some renown, 'Ādnān ibn

al-'Aynzarbī (d. 548/1153). The relevant biographical dictionaries mention Ibn Jumay''s talents in medicine as well as his highly developed linguistic consciousness, inducing him always to carry al-Jawharī's *Kitāb aṣ-ṣaḥāḥ* (The Truthful Guide) to class so he could check words of which he was uncertain. Ibn Jumay' died in 594/1198.

In Ibn Abī Uṣaybi'a's dictionary of medical doctors, '*Uyūn al-anbā' fī Ṭabaqāt al-aṭibbā'* (Sources of Information About the Classes of Physicians), Ibn Jumay' is presented as the author of eight works on medical or medicine-related subjects, the most important of them being *Kitāb al-irshād li-maṣāliḥ an-nufūs wa 'l-ajsād* (Guide to the Welfare of Souls and Bodies), a compendium of the different fields of the art of medicine. Others also deal with practical questions of the doctor's craft such as first aid or nutritive advice.

The only one of Ibn Jumay''s works published to date, al-Maqāla aṣ-ṣalāḥīya fī iḥyā 'aṣ-ṣinā 'a aṭ-ṭibbīya (Treatise to Ṣalāh ad-Dīn/Saladin on the Revival of the Art of Medicine), is not mentioned by Ibn Abī Uṣaybi'a. It is a deontological work, i.e., it deals with the doctor's profession on a more theoretical level.

This treatise, as Ibn Jumay' mentions in the introduction, owes its composition to a conversation he had with his sovereign on the deplorable state of medicine in his time, the reasons for this, and ways to ameliorate the situation. Thus, formally the work stands in the literary tradition of the epistle, a genre frequently employed by Ibn Jumay' in other works and by Arabic medical authors in general. Its contents – the complaints about the declining state of the art and considerations about its improvement – were not unknown in his time either. The theme goes back to Galen or even Hippocrates.

The treatise falls into three chapters: Chapter 1 concerns the presentation of medicine, including the qualities of medicine and the need for it, as well as the difficulties of medicine and their consequences; Chapter 2 deals with the reasons for the decline of medicine, including a brief presentation of its history; and Chapter 3 suggests ways to revive the art of medicine.

Whereas compendia of a more technical presentation of medicine in medieval Arabic literature are comparatively numerous, the same cannot be said about this kind of work, with its introductory and deontological character. In that lies the importance of this doctor of the twelfth century AD, Ibn Jumay'.

- and raised in Tunis, he read the *Qurʿān* and studied the religious sciences as well as Arabic and poetry, then was educated in logic, mathematics, natural science, and metaphysics. He also received specialized training in court correspondence and administrative matters, subjects that allowed him to become a court secretary to the Marinid ruler Abū ʿInān in Fez at about the age of 22.
- After some vicissitudes, including almost 2 years of prison, Ibn Khaldūn went to Grenada in 1362 to become an advisor and tutor to Muḥammad V. That position lasted only about 2 years, no longer than his subsequent position as prime minister or *Hājib* to Prince Abū ʿAbd Allāh of Bougie. Following these forays into practical politics, Ibn Khaldūn endured several years of upheaval (1366/1766–1375/1776), settled for about 4 years in Qal ʿat Ibn Salāma near Oran and began work on his history, then moved to Tunis under the patronage of Abū al-ʿAbbās in order to have access to documents and libraries. After a few years there, court intrigues led him to seek tranquility in Egypt.
- During the next quarter of a century he served the Mamlūk Sultān Barqūq as judge (*qāḍī*) and chief judge (*qāḍī al-quḍā*), professor at various universities (including the prestigious al-Azhar), and one time university president. A few years before his death he met with the famous Mongol chieftain Tamerlane. But the period in Egypt was, above all, a time for revising his *Kitāb al-ʿIbar* and working on the Introduction (*Muqaddima*) to it.

Ibn Khaldūn

Charles E. Butterworth

ʿAbd al-Raḥmān ibn Khaldūn (1332/1732–1406/1808) spent the first two-thirds of his life in North Africa and Muslim Spain, fleeing in 1382/1784 to Egypt, where he remained until his death. Though he is best known for the lengthy Introduction (*Muqaddima*) to his massive philosophical history of civilization (*Kitāb al-ʿIbar*), Ibn Khaldūn spent much of his life in political activities. Born

The *Kitāb al-ʿIbar* is a multivolume effort that, in his words, sets forth “the record of the beginning and the suite of the days of the Arabs, Persians, Berbers, and the most powerful of their contemporaries.” Its Introduction consists of six very long chapters that explore the character of human civilization in general and Bedouin civilization in particular, as well as the basic kinds of political associations, and then the characteristics of settled civilization, the arts and crafts by which humans gain their livelihoods, and, finally, the different human sciences. Ibn Khaldūn starts by

explaining the merit of history and how to go about writing it. Properly speaking, the reason to write history or the “inner meaning of history” is, by means of reflection, to get “at the truth, subtle explanation of the causes and origins of existing things, and deep knowledge of the how and why of events.” Though his enterprise is therefore “rooted in philosophy” and to be considered a branch of it, Ibn Khaldūn acknowledges a problem with the way history has come down. Many unqualified people have trammelled with the books of history written by competent Muslim historians; they have introduced tales of gossip imagined by themselves as well as false reports. Moreover, other historians have compiled partial reports of particular dynasties and events without looking to the way things have changed over time, without looking at natural conditions and human customs. Consequently, Ibn Khaldūn considers his task to be that of showing the merit of writing history, investigating the various ways it has been done, and showing the errors of previous historians. What needs to be known, and thus what he sets out to make known, are “the principles of politics, the nature of existent things, and the differences among nations, places and periods with regard to ways of life, character, qualities, customs, sects, schools, and everything else ... plus a comprehensive knowledge of present conditions in all these respects ... complete knowledge of the reasons for every happening and ... [acquaintance] with the origin of every event.” Yet in the end Ibn Khaldūn hints that he has almost digressed in the whole undertaking. What he wanted to do was to explain the nature of civilization and its accompanying accidents, but he fears he has strayed from his basic point.

Ibn Khurdādhbih

Sayyid Maqbul Ahmad

Abu'l-Qāsim 'Ubayd Allāh ibn Khurdādhbih (also spelled Ibn Khurradādhbih), the first scholar to write on world geography in Arabic, was born in ca. AH 205/AD 820 (or AH 211/AD 825), and died in ca. AH 300/AD 912. Probably born in Khurāsān, he was brought up in Baghdad. His grandfather, Khurdādhbih, was a Zoroastrian, latter converted to Islam, and his father was the governor of Ṭabaristān. When he grew up, he became the director of posts and information in Jibāl (Media) and subsequently became director-general of the same department in Baghdad and later in Sāmarrā (Iraq). He became a companion of the 'Abbāsīd Caliph al-Mu'tamid (AH 256–279/AD 870–892).

Ibn Khurdādhbih was a versatile writer; besides writing on geography, he wrote on history, genealogy, music, wines, and even on the culinary art. Al-Nadīm, in his *al-Fihrist*, lists at least eight works to his credit. The Arab historian Abu'l-ḥasan 'Alī ibn al-ḥusayn al-Mas'ūdī (d. AD 956) considered him an *imām* (leader) in authorship and mentions his voluminous historical work dealing with the ancient kings and peoples of Iran (*Murūj* 1965). Ibn Khurdādhbih also claimed to have translated into Arabic the geographical treatise of Claudius Ptolemy (ca. AD 90–168) from a “foreign language” (probably Syriac or Greek), but the translation is not extant.

However, Ibn Khurdādhbih's major work on geography, entitled *Al-Masālik al-Mamālik* (Roads and Kingdoms), was published by M. J. De Goeje in 1889. In fact, this work is an abridgement (prepared not later than AD 885–886) of his larger work (not extant) written in ca. AD 846–847. Considering the vast amount of information contained in the work and the early date of its compilation, it may be said that Ibn Khurdādhbih was the father of Arab-Islamic geography; no work of such magnitude existed

before him. *Al-Masālik al-Mamālik* deals briefly with mathematical and physical geography, but the major portion of the work is devoted to descriptions of land and sea routes in the four directions emerging from al-Sawād. Then, it deals with marvels of the world, seas and mountains, sources of the rivers, and reports on countries like India and Central Asia.

It is not unlikely that Ibn Khurdādhbih relied heavily for his information on the ancient Sassanian government records which must have become available to him as the person in charge of the department of posts and information in Baghdad and elsewhere. Again, in his methodology and arrangement of the material and in the use of geographical terms and Persian couplets, a distinct Persian influence is discernible. The ancient Persians used to divide the known world into seven circular regions called *kishvars* (kingdoms) with Irānshahr at the center and the remaining six circles drawn around it. Such an arrangement is observable in his descriptions of the various routes emerging from al-Sawād, which, he says, was called *dil-i Irānshahr* (the heart of Iraq).

Ibn Khurdādhbih was not only the first to write on geography in Arabic, but he also set the style for writing on descriptive geography. Several later Arab-Islamic geographers utilized his work as a major source of information.

Ibn Mājid

Sayyid Maqbul Ahmad

Shihāb al-Dīn Aḥmad ibn Mājid ibn Muḥammad ibn Amr ibn Faḍl ibn Duwayk ibn Yūsuf ibn Ḥasan ibn Ḥusayn ibn Abī Ma'laq al-Sa'dī ibn Abu'l-Rakā'ib al-Najdī was the greatest Arab navigator of the fifteenth century AD and one of the greatest of the Middle Ages. We do not know the date of his birth or death, but he must have died at an advanced age sometime in the first decade of the sixteenth century. Born in Julfār (Oman), he belonged to an illustrious family of navigators. Both his father and grandfather were *mu'allims* (masters of navigation) of repute.

Ibn Mājid wrote a number of works, both in prose and poetry, on nautical theory and on describing the seas (mainly the Indian Ocean) which served as guides for the Arab navigators of later periods. Among his important works in prose is the *Kitāb al-fawā'id fī 'uṣūl'ilm al-baḥr wa'l-qawā'id* (The Book of Benefits on the Principles of the Science of Navigation), dated AH 895/AD 1489–1490. This book and many others have been reproduced in the editions mentioned in the bibliography.

Ibn Mājid considered himself the fourth of the great Arab navigators of the Middle Ages; the other three were Muḥammad ibn Shādān, Sahl ibn Abān, and Layṭ ibn Kahlān, who belonged to the Abbāsīd period. He thought his own works were more accurate than theirs, since they were more current and since many of the ports mentioned in the older works no longer existed. Apart from his practical experiences as a navigator, he had studied and improved upon the work of his father (*al-ḥijāzīya*) and had studied a number of

earlier Arabic works on astronomy and geography.

On the practical side of navigation, it is not unlikely that Ibn Mājid was in contact with the Indian navigators of his time, the *Ṣūliyān* (Cholas of Tamil Nadu, India) and with the Gujarati and the Konkani (Maharashtra, India) navigators, whose *qiyāsāt* (readings of the ports and harbors) he seems to have known. He was particularly knowledgeable about Siam and Bengal, and these navigators frequented these regions more than the Arab navigators did.

In his works Ibn Mājid covered a number of subjects relating to navigation, nautical astronomy, oceanography, and geography. In his *Kitāb al-fawā'id*, he pays special attention to subjects of a more general nature, like guidelines to navigators such as the prerequisites for sailing on the sea, and he describes the lunar mansions, the stars corresponding to the 32 divisions (*aqnān*) of the compass card, the winds and seasons of the seas, nautical instruments, and the essentials required by captains of boats. These include knowledge of the rising and corresponding settings of the stars (*al-anwā'*), latitudes and longitudes, landfalls, and tides. He emphasizes that before sailing, captains should see that their instruments are in perfect order, the sailors obedient, and the seasons suitable. They should be patient and soft-spoken, should not deprive merchants of their rights, and they should be courageous, literate, and well behaved. He also presents a systematic description of the sea coasts of the Oikumene (the known world at that time), which no geographer had done before. From his writings, it appears that he did not conceive that a *terra incognita* existed in the southern quarter of the earth, as other geographers of his time believed. He thought that the Indian Ocean was connected with the Atlantic through a sea channel, which he calls *al-madqal* (place of entry).

Ibn Mājid claimed to have made several contributions to navigation and to determining the direction of the *qibla* (Mecca) from different positions of the earth with the help of the compass card. He also claimed to have fixed a magnetized needle on the mariners' compass (probably on a day box). Ibn Mājid had met Vasco da Gama, and

had guided him to Calicut, India. Although the Portuguese sources do not mention him by name in this regard, we know from an Arabic work, *al-Barq al-Yamānī fī'l-faṭḥ al-ʿUṭmānī* (The Yemenite Lightning on the Ottoman Conquest) by al-Nahrawālī that it was he who directed Vasco da Gama from Malindi (East Africa) to India.

Ibn Māsawayh

Danielle Jacquart

Abū Zakariyyā' Yūḥannā ibn Māsawayh was born in Baghdad during the caliphate of Hārūn ar-Rashid (786–809), and not in 777 as was stated by ► [Leo the African](#). His father, Māsawayh, was a pharmacist in the service of the physician Jibrāʾīl ibn Baḥtishū', with whom he came from Jundīshāpūr (in Persia) to Baghdad. His mother

was a slave, named Risala, whom Māsawayh bought from the physician Dawūd ibn Sarābiyūn. Thus, Yūḥannā ibn Māsawayh belonged to the milieu of Christian Nestorian physicians, who played an important part during the eighth and ninth centuries. He married the daughter of his colleague Abdallāh at-Tayfūrī and had a son of poor intelligence. He was very famous as a teacher and practitioner; he became the personal physician of four successive caliphs from al-Ma'mūn to al-Mutawakkil. He died in Samarra in 857.

As for many other authors of this period, it is difficult to distinguish legend and history in his biography. It was said that he did translations from Greek into Arabic, but none is extant under his name; most probably, he only commissioned some of them. For instance, it is well attested that ► [Ḥunayn ibn Isḥāq](#) undertook the translation of Galen's *Methodus medendi* (Arabic *Kitāb hīlat al-bur'*; Methods of Healing) at Ibn Māsawayh's request. The relationship between both physicians was nevertheless strained, at least at the beginning: Ibn Māsawayh is supposed to have driven Ḥunayn out of his teaching position, who then went traveling in order to learn Greek and purchase manuscripts. It was also reported by Arabic medieval historians that Ibn Māsawayh had the opportunity of dissecting an ape, which had been given to the caliph by the prince of Nubia in 836 as a present. Following in Galen's footsteps Ibn Māsawayh afterward wrote an anatomical monograph, which can perhaps be identified with his *Kitāb at-tashrīḥ* (Book of Anatomy). Apart from his knowledge of Greek medicine, Ibn Māsawayh had access to some Indian works: he quotes, for instance, ► [Āryabhata](#) in his ophthalmological treatise *Kitāb daḡal al-ʿain* (Book on the Defectiveness of the Eye).

Ibn Abī Uṣaybi'a listed 42 works; some others were quoted by ► [al-Rāzī](#) and ► [al-Bīrūnī](#). But only 31 are extant, as far as we know, and very few have been edited or studied. Those that have been edited – and sometimes translated into English or French – are the *Aphorisms*, the works on barley water, simple drugs, and perfumes, as well as the medical calendar; the

ophthalmological treatises have also been analyzed. It seems that among the works which were translated into Latin during the Middle Ages under the names of "Mesuē" or "Johannes Damascenus," only the *Aphorismi Johannis Damasceni* and some ophthalmological fragments can be attributed to Ibn Māsawayh; the other ones, mainly pharmacological, are probably apocryphal for the most part. The *Aphorismi* – a faithful translation of *Nawādir at-ṭibb* – were largely diffused from the twelfth century; a second translation appeared as the sixth book of Rāzī's *Secrets of Medicine*: it was done during the thirteenth century by the Dominican Giles of Santarem.

Some original features of Ibn Māsawayh's medicine can be drawn from his *Nawādir at-ṭibb*. Dedicated to Ḥunayn ibn Isḥāq and modeled on the Hippocratic *Aphorisms*, this short work was intended to give practical advice. The eight first aphorisms can be considered as a kind of commentary on the first Hippocratic aphorism: "Life is short, art long, opportunity fleeting, experiment dangerous, judgment difficult." They stressed the necessity for physicians to be both learned and skilled. Throughout the remaining 124 aphorisms the following topics are covered: the link between body and soul, the observance of astrological and climatological rules, the attention that physicians have to pay to the healthy nature of their patients, the numerical ratios which rule human temperaments, as well as natural substances used for treatment. It has to be noted that this last idea was deeply developed by Ibn Māsawayh's contemporary, ► [al-Kindī](#). Ibn Māsawayh seems also to have been very much attached to the idea that physicians must mainly reinforce nature by using drugs similar to it; medical treatment with substances contrary to disease had to be prescribed cautiously and their sole goal was to purge. Physicians had to be cautious not to alter nature too much. For example, Ibn Māsawayh stated: "It is important that, against diseases, the strongest contrary is not introduced into the body, since this would be very harmful; it can be compared with a very cold wind which, during the same day, blows after a very hot one" (aph. 60). In the

same manner, treatment by diet was preferred to pharmacopoeia: "If the physician can treat with food, to the exclusion of drugs, he will be very successful" (aph. 108). In addition to several pharmacological treatises, Ibn Māsawayh composed an important work on dietetics.

Ibn Māsawayh's works remain very little known, despite their importance in the history of Arabic medicine. Detailed studies would shed light on the decisive stage constituted by the beginning of the ninth century, before the spread of Ḥunayn's translations.

Ibn Mu'ādh

A. Mark Smith

University of Missouri, Columbia, MO, USA

Ibn Mu'ādh al-Jayyānī, Abū 'Abd Allāh Muḥammad (d. ca. 1093) has traditionally been assigned a birth date of 989. However, recent scholarship suggests that Ibn Mu'ādh was born somewhat later, in the early eleventh century. The only secure date we have for him is 1079, the year of a solar eclipse he describes from firsthand observation. The ending "al-Jayyānī" to his name indicates that he was from Jaén in Andalusia, where he evidently served as a *qāḍī* (judge) for much of his life. Among his few surviving astronomical and mathematical works are included the *Tabulae Jahen*, a set of astronomical tables based on those of al-Khwārizmī and probably translated into Latin by Gerard of Cremona; *Maqāla fī sharḥ al nisba* (On Ratio), a commentary on Book 5 of Euclid's *Elements*; and *Kitāb majhūlāt qisiyy al-kura* (Determinations of the Magnitudes of the Arcs on the Surface of a Sphere), a work on trigonometry. Certainly the most original, and perhaps the most historically significant of his extant works, is the brief treatise *On Twilight and the Rising of Clouds*.

While no Arabic exemplar has yet come to light (the original title was probably *Ma'l-fajr wa'l-shafaq*), this work has nonetheless reached us in three other linguistic forms: a fourteenth-century Hebrew translation from the Arabic (represented by 1 manuscript), a late twelfth-century Latin translation from the Arabic, probably by Gerard of Cremona (represented by 25 manuscripts), and a fourteenth-century Italian translation from the Latin (represented by 1 manuscript). The sheer number of Latin manuscripts – plus the Italian translation – indicates the seriousness with which this treatise was received and disseminated in the medieval West. That it was commonly misattributed to Ibn al-Haytham, author of the magisterial *Kitāb al-manāẓir* (*De aspectibus*),

may have had something to do with this. There is also clear, albeit indirect, evidence that *On Twilight* exerted its share of influence in the medieval East as well.

Ibn Mu'adh's purpose in *On Twilight* is to determine the height of the atmosphere under the assumption that the first light of dawn is produced when rays from the rising sun tinge vapors at the very upper edge of the atmosphere. Although he offers no practical justification for this inquiry, he does, in a couple of querulous asides, berate those (religious conservatives?) who would squelch rational inquiry out of mere ignorance. The determination itself depends upon four basic parameters: the depression of the sun below the horizon at first light (18°), the mean distance between the earth and sun (1,110 terrestrial radii), the relative size of the sun and earth (5.5:1 in terrestrial radii), and the circumference of the earth (24,000 mile). On the basis of these parameters and using simple trigonometric functions, Ibn Mu'adh calculates the atmosphere to be around 52 miles high. This figure remained canonical in the Latin West until the end of the sixteenth century, when Tycho Brahe raised the issue of atmospheric refraction to prominence. Within this context, it soon became clear that Ibn Mu'adh's calculation was useless because it failed utterly to take atmospheric refraction into account. Consequently, his figure of 52 miles was drastically reduced by Johan Kepler and succeeding astronomers.

Ibn Mun'im

Ahmed Djebbar

The oldest mathematical work from the Maghreb which deals with combinatory problems is the *Fiqh al-ḥisāb* of Ibn Mun'im, a scholar originally from Andalusia, living in Marrakesh in the Almohad era. To our knowledge, his book was the first in the entire history of mathematics to have devoted a whole chapter to these types of problems and to have stated them and solved them according to a common procedure.

Aside from Ibn 'Abd al-Malik, the biographers of the Maghreb do not mention Ibn Mun'im, even though they write at length about mathematicians of lesser significance, and they use the contents of his book. The little information we do have on Ibn Mun'im comes from his own introduction to his mathematical text, cited above, and from the book of Ibn 'Abd al-Malik.

According to the latter source, Ibn Mun'im's full name was Aḥmad ibn Ibrāhīm ibn 'Alī Ibn Mun'im al-'Abdarī. He was originally from the town of Denia on the east coast of Spain, near Valencia, and he lived in Marrakesh where he taught and where he died in 626H/1228. He was

known as one of the best scholars of his era in geometry and number theory. At the age of 30, he began to study medicine which he practiced successfully at the same time as his mathematical activities.

Only three of Ibn Mun'im's numerous mathematical texts and letters are known today: one on magic squares, another on geometry, and the third on the science of calculation. And of these, only the last, *Fiqh al-ḥisāb*, is extant. Ibn Mun'im wrote it under the reign of the fourth Almohad caliph, al-Nāṣir (1199–1213). During his reign celebrated scholars like the grammarian Abū Mūsā al-Jāzūlī, the algebraist ► [Ibn al-Yāsāmīn](#), and the doctors of the Ibn Zuhri family all lived in the Almohad capital, or even within the court itself. This leads one to believe that there was a variety of scientific activity, thanks to a generous and often enlightened patronage.

Combinatory analysis is taken up the 11th section of the first chapter of *Fiqh al-ḥisāb*, entitled “an accounting of words which are such that human beings can express them only by one of them.” This section is not, however, in the eyes of this author, a complete overview of practical calculations. He takes care to explain, in the course of his exposition, that he proposes first to treat the problem in a general manner, even though he is obliged, in order to make his ideas clear, to formulate it in specific terms using the Arabic alphabet. In fact, this study goes beyond the linguistic framework in which it is formulated, as much by the way of posing the problems and linking them to each other, by the methods of reasoning used, as by the established results.

Ibn Mun'im begins by setting out the problem as a mathematician; he defines precisely the framework in which he is stating the chosen hypotheses and the degree of generality researched. Then he establishes, using a set of colors of silk as an abstract model, a rule which enables one to determine all the possible combinations of n colors p times p . In order to do that, he constructs, in accordance with an inductive method, a triangular numeric table, identifies its elements, with the desired combinations, and deduces the relationships:

$$C_n^p = C_{n-1}^{p-1} + C_{n-2}^{p-1} + \cdots + C_{p-1}^{p-1}.$$

Thus, he presents, to our knowledge for the first time, the famous arithmetical triangle which algebraists from the Muslim East like ► [al-Karājī](#) (d. 1029) had already constructed but for other purposes and using another procedure.

Ibn Mun'im's study continues by establishing, using induction, relative formulas with permutation, with or without repetitions, of a group of letters such that they give, by recurrence, the number of possible readings of a word of n letters, taking into account all the signs (vowels and sukūns for Arabic) used by a given language. This is the content of problems 2, 3, and 4. In problem 5, the author concludes the first part by establishing a formula of arrangements, without repetition, of n objects p times p , which take into account the vowels and the sukūn accompanying the letters.

The second part, much longer, seeks to enumerate the combinations with repetitions, adopting a method analogous to the preceding one and which necessitates recourse to the table of numbers. It was moreover this same method that the French scholar Mersenne rediscovered and applied to his work in the seventeenth century.

To set up problem 6, Ibn Mun'im goes back to his model of bunches and proposes to solve a difficult dilemma, apparently removed from the initial problem and stated thus: being given threads of silk in n colors, we want to determine the number of bunches it is possible to make with p threads of k colors, so that $p_1, p_2, \dots, p_k$ threads are, respectively, of the same color.

All these propositions, and even more the techniques, allow the resolution of the problem which Ibn Mun'im formulates as follows: to determine the number of words of one to ten letters which it is possible to make with the letters of the Arabic alphabet, including all possible repetitions of letters in a words, and including vowels and the sukūn which can appear on letters.

The third part of his study includes, along with several applications, a series of tables which

enables the determination, more and more closely, of all the elements (P_n , A_n , C_n , ...) which occur in the counting of words that it is possible to pronounce in a given language.

In addition to the results included in this chapter of *Fiqh al-hisāb*, the way in which Ibn Mun'im established his results is also notable. In fact, he uses two types of reasoning which can be called inductive and combinatorial. While inductive reasoning is a traditional tool of Islamic mathematics with its privileged domains and unique stature, one cannot say the same for combinatorial reasoning which appeared, to our knowledge for the first time, in the *Fiqh al-hisāb*. His systematic use of combinatorial reasoning for establishing general propositions appeared as a clear acknowledgment of its mathematical character.

One can even suppose that if combinatorial reasoning had enjoyed a quantitative development in the field of application, it would have resulted in its explicit recognition as a process of reasoning beside analysis, synthesis, induction, and reasoning *ad absurdum*.

The elaborate nature of his procedures and results which appear in the *Fiqh al-hisāb*, as well as the spirit of the method which emerged from them leads to the theory that the beginning of the mathematization of combinatorial problems within the framework of Arabic science occurred prior to the work of Ibn Mun'im.

While we await the confirmation, or correction, of this conjecture, the *Fiqh al-hisāb* remains the oldest known Arabic work from the Muslim West in which an autonomous chapter on combinatorial analysis appeared. But its importance does not end there: with regard to the linguistic tradition of the Maghreb, the book was a culmination in that it laid out a general solution to a given problem. Also, for mathematics, the work represents an important link, marking the end of one stage in the progress of combinatorics, that of calculation using tables, and the beginning of another stage, that of the extension of formulas and their use in solving problems.

Ibn Qunfudh

Y. Guergour

Abū'l'Abbās Aḥmed Ibn al-ḥasan Ibn 'Alī Ibn al-Khaṭīb was known under the two names of Ibn Qunfudh and Ibn al-Khaṭīb. He was born in 710 AH (AD 1339) in Constantine, Algeria and came from an old family which was cultured and well to do. We know that Ibn Qunfudh began his studies with his father and his maternal grandfather, in order to follow them eventually under the direction of other professors from his same town.

After his elementary education, he returned to Fez, in Morocco, where he remained for 18 years. There he studied with several professors, covering different scientific themes, and teaching and publishing some of his own work. We know that it is in this city that he edited in 771 (1370) his most important mathematical work, the *Ḥaṭṭ an-niqāb' an wujūh' amāl al-hisāb*, which is a commentary on the *Talkhīṣ a'māl al-hisāb* of ► [Ibn al-Bannā'](#), written in 721 (1321). We think that he acquired his advanced education either completely or partially during his stay in Fez.

During the period of famine which raged in all of Maghreb in 776 (1374), Ibn Qunfudh went back to Constantine in order to take up duties as a *khaṭīb* (preacher), *muftī* (jurist), and

qāḍī (judge). At the same time, he devoted himself to the teaching and editing of scholarly work. No information has come down to us on the subject of the contents of this teaching, and we do not even know if he taught the contents of his own mathematical writings at Constantine or in the cities where he was posted, or even if he was content only to edit them, following in that the tradition of several older authors, who wrote on subjects which were very different from each other without having taught them.

What follows is an attempt to give a glimpse of Ibn Qunfudh's contributions to mathematics, of which we know only four titles:

1. *Mabād' as-sālikin fī sharh rajz* ► [Ibn al-Yāsāmīn](#) (Principles for Those who are Concerned with the Commentary on the Poem of Ibn al-Yāsāmīn). Ibn Qunfudh began this poem according to the traditional procedure of commentators of the Middle Ages. What is not traditional is his use of mathematical symbolism to resolve equations and to represent polynomials. This was to become normal practice during this period, since this commentary was adopted by his students. The symbolism was universally used in mathematical works from Maghreb. This hypothesis is reinforced by the presence of this same symbolism in the book *Ḥaṭṭ an-niqāb* and in the book written by Ya'qūb al-Muwāḥidī *Tahṣīl al-munā fī sharh Talkhīṣ Ibn al-Bannā*.
2. *Bughyat al-fāriḍ min al-ḥisāb wa l-farā'id* (The Desire of the Genealogical Specialist to Know Arithmetic and Successional Division). To this day, no copy of this book has been found.
3. *at-Talkhīṣ fī shzarh at-Talkhīṣ* (Abridged Commentary on *Talkhīṣ*). This is a resume of *Ḥaṭṭ an-niqāb*, of which two copies are extant today.
4. *Ḥaṭṭ an-niqāb'an wujūh' amāl al-ḥisāb* (Lifting the Veil on the Operations of Calculation). Five copies of this work are extant.

Since this is Ibn Qunfudh's most important work, it is useful to describe certain aspects of

its contents. Reading it permits us to make several important observations on mathematical writing in this era. The author begins his book with some advice and directions designed to facilitate the reading of any book; then he provides a detailed list of the writings of Ibn al-Bannā'. In the beginning of each chapter, he gives an abstract of its contents, something which one finds nowhere else in the literature of other mathematicians of this time. It is also important to note again the existence of Ibn Qunfudh's mathematical symbolism, particularly in the chapters on roots and on algebraic equations. However, recent research reveals that this symbolism had been used previously at the end of the twelfth or beginning of the thirteenth century, especially in Ibn Yāsāmīn's book *Talqīḥ al-afkār*. Elsewhere, Ibn Qunfudh supplies arithmetic rules which one does not find in Ibn al-Bannā''s work, notably in the chapter on the product. Ibn Qunfudh's terminology also differs significantly from Ibn al-Bannā''s.

Finally, one finds in the work of Ibn Qunfudh an equation of which the second number is zero, an equation which had formerly been studied by Ibn Badr. His originality lies in the symbolic way in which he expressed it:

$$0 \text{ ج } 7 \text{ ي } 8.$$

or, in modern symbols, $8.r - 7 = 0$.

Ibn Qunfudh died in 810 AH (AD 1407).

Ibn Qutayba

Paul Kunitzsch

University of Munich, Munich, Germany

Ibn Qutayba, Abū Muḥammad 'Abdallāh ibn Muslim, was born in 828 in Kufa or Baghdad, and died in 884 or 889 in Baghdad.

Ibn Qutayba was a scholar of typical Arabic-Islamic education. His studies included all branches of the traditional Arabic and Islamic knowledge of his time: religion, history, biography, philology, lexicography, literature, and some science. He left 20 works of varying lengths covering all the fields mentioned. In his career, for some years he was *qāḍī* (a judge according to Islamic rules) in Dinawar (northern Iran); later he lived and taught in Baghdad, where he also died. Of particular scientific interest is his *Kitāb al-anwā'* (Book on the *anwā'*). *Anwā'* are asterisms and stars used by the Arabs in pre-Islamic and early Islamic times to determine seasons, predict weather-especially rain, and guide them in their nightly desert travels. Many Arabic philologists and lexicographers wrote books of this type, but most of these did not survive. Therefore Ibn Qutayba's *Book on the anwā'*, which was printed in Arabic, in Hyderabad/Deccan (India) in 1956, is of great interest. In it, the author has

assembled information on the popular astronomical and meteorological knowledge of the old Arabs, from the time before their acquaintance with Greek, Persian, and Indian astronomy. Facts, traditions, terminology, and nomenclature are amply described. Much of this material continued to be used later in the most active period of Arabic – Islamic astronomy. And some of it even lived on into our time, as, for example, the star name Aldebaran (for α Tauri).

Ibn Riḍwān

Albert Z. Iskandar

Abu'l-ḥasan 'Alī Ibn Riḍwān 'Alī Ibn Ja'far, a self-educated physician philosopher, was born in AD 998 at Gīzah, a suburb south of Cairo (al-Fuṣṭāṭ). He was the son of a poor baker (*farrān*) and had to earn money in his youth by practicing medicine, teaching, and telling people's fortunes from astrological signs. When he was 59, he wrote a book entitled *Fī Sīratihī* (On His Own Conduct). The work is now lost, but its text is partly preserved in Ibn Abī Uṣaybi 'a's *'Uyūn al-Anbā' fī Ṭabaqāt al-Aṭibbā'* (Sources of Information About the Classes of Physicians).

In his youth, he believed in astrology (*'ilm al-nujūm*) and was convinced that the stars at the time of his birth indicated a prosperous medical career. To realize his ambition, he first sought out a popular teacher in Cairo, who instructed Ibn Riḍwān to memorize Ḥunayn Ibn Ishāq's

(d. AD 873) *Kitāb al-Masā'il fi'l-Ṭibb li'l-Muta'allimīn* (Questions on Medicine for Students). Ibn Riḍwān watched him teaching: pupils read the text; the teacher listened but did not utter one word of explanation and did not even bother to correct their errors. Ibn Riḍwān sought to find other teachers and put questions to each of them, based on the writings of Hippocrates and Galen, which they displayed on shelves in their private libraries. He concluded that they merely knew the titles of books but were ignorant of their contents. He pondered over traveling to Iraq for further education, but financial difficulties prevented his going there. He decided on self-education at the tender age of 15. From perusing Galen's *On the Doctrines of Hippocrates and Plato*, he concluded that he should first study geometry and logic. He studied the well-known books on these two subjects, then proceeded to read textbooks on medicine proper. In this way he reached an understanding of the principles of the art of healing.

Ibn Riḍwān worked very hard as a practicing doctor until he reached the age of 32, when he became well known and earned enough money to build his own residential Palace of Candles (*Qaṣr al-Sham'*). At the age of 59 he divided his time between practicing medicine, daily physical exercise (*al-riyāḍah*), and reading books on literature, Islamic law, and medicine. His fame reached the Fātimid Caliph al-Mustaṣhir (r. AD 1036–1094), who appointed him Chief of Physicians (*Ra'īs al-Aṭibbā'*) in Egypt. He was kind-hearted, treated the poor for free, and was always willing to extend a helping hand to the needy.

In old age, Ibn Riḍwān's mind became disturbed (*taghayyar 'aqluhu*) as a result of being robbed of all his cherished possessions. He had adopted an orphan young girl whom he brought up in his own house. She absconded with all the precious items he had accumulated and 20,000 gold dīnārs which he had kept in the house. An extensive search for the girl was abortive. Ibn Riḍwān died in AD 1067.

Among Ibn Riḍwān's extensive bibliography are his treatise *Fī Daf' Maḍārr al-Abdān fī Arḍ Miṣr* (On the Prevention of Bodily Ills in Egypt)

and the *Al-Nāfi' fī Kayfiyyat Ta'līm Ṣinā' at al-Ṭibb* (Useful Book on the Quality of Medical Education).

In *On the Prevention of Bodily Ills*, he describes the Nile and the Muqaṭṭam Hills on both sides of the river. The hills in the east hold back the "hot and humid" winds, which are most favorable for the temperament (*mizāj*) of animals and which do not reach *al-Fuṣṭāṭ*. Ibn Riḍwān gives an account of "the six non-natural causes" (*al-asbāb al-sitta al-ḍarūriyya*) which determine health and sickness: the air surrounding the body, food and drink, movement and rest, sleep and wakefulness, retention and evacuation, and psychic events.

Ibn Riḍwān was discourteous in criticizing members of the medical profession. For example, Chapter 5 of this treatise is entitled "On the Incorrectness of Most of Ibn al-Jazzār's [d. AD 1009] Reasons for the Unhealthy Air in Egypt." Furthermore, disagreements arose with ► [Ibn Buṭlān](#) of Baghdad. These are well documented by Meyerhof and Schacht (1937).

In his *Useful Book*, Ibn Riḍwān preserved for posterity a unique document, the late Alexandrian medical curriculum (sixth to seventh century AD). In it he attributes the decline of medicine in his time to the popularity of poor-quality compendia (*kanānīsh*) and summaries and commentaries of the books of Hippocrates and Galen, compiled by incompetent physicians. The Alexandrian curriculum specifies the titles of textbooks of logic, medicine proper, and mathematics (including astronomy). It consists of preparatory (introductory) courses and main courses. The preparatory courses contain optional subjects, including language and grammar, and compulsory subjects: physics, arithmetic, numerals, measurement, geometry, the compounding of drugs, astrology, and ethics.

The main courses include logic and medicine proper. Sixteen of Galen's books were to be studied in seven grades: Grade 1 included Galen's *On Sects*, *On the Art of Physics*, *On the Pulse*, *To Teuthras*, and *To Glaucōn on Therapy*. In the final and seventh grade, students studied Galen's *On the Method of the Preservation of Health*.

Ibn Rushd (Averroës)

Albert Z. Iskandar

Abu'l-Walīd Muḥammad ibn Aḥmad ibn Muḥammad ibn Rushd (Averroës, AD 1126–1198), a native of Cordoba, Spain, was the namesake of his famous grandfather. Later, to avoid any confusion, he was nicknamed *al-ḥafīd* (grandson). Like his father and grandfather, he was a well-known jurist. By profession, following in the footsteps of his father, he became a *qāḍī* (judge), who specialized in religious matters, and at one time was the Imam of the great mosque of Cordoba. He adhered to the Mālikī sect, one of the four great sects of Islam, and

wrote *Kitāb al-Muqaddimāt al-Mumahhidāt* (A Book of Introductions that Pave the Way), for the followers of the sect.

At his father's insistence, Ibn Rushd studied Islamic law (*Shari'ah*) under the teacher, al-ḥāfiẓ Abū Muḥammad Ibn Rizq. Ibn Rushd also studied the science of Tradition (*Ḥadīth*), but he is known to have been more interested in Islamic law. He memorized the *Muwatta'* of Imam Mālik and was also greatly impressed by the Ash'arite science of Kalām (Theology). Later, he turned against the Ash'arī school of thought and attacked its proponent, the Imam al-Ghazālī (d. AD 1111). Ibn Rushd was also acquainted with the doctrines of the Mu'tazila theology.

His teachers of medicine were Abū Marwān Ibn Jurrayūl, a first-class practitioner, and Abū Ja'far Hārūn al-Tarjālī, a well-known physician philosopher in Seville, who was knowledgeable about Aristotelian philosophy, as well as the medical writings of the Ancients. Al-Tarjālī was employed by the Almohad (*al-Muwahḥid*) ruler Abū Ya'qūb Yūsuf (r. AD 1163–1184). Abū Yūsuf Ya'qūb al-Manṣūr (r. AD 1184–1199), before succeeding his father, attended meetings in Seville, to which notable philosophers, physicians, and poets were invited. Abū Bakr Ibn Ṭufayl (Abubacer), Ibn Zuhr (Avenzoar), and Ibn Rushd were regular attendants at these meetings. Ibn Rushd's education under al-Tarjālī qualified him as a physician-philosopher; his studies in religious law, under al-ḥāfiẓ, entitled him to be considered a jurist (*faqīh*).

In 1153, when he was in Marrakech (Morocco), Ibn Rushd supported the Almohad ruler 'Abd al-Mu'min (d. AD 1163) in furthering education by founding colleges. From his commentary on Aristotle's *De Caelo*, one learns that Ibn Rushd conducted astronomical observations when in Marrakech, and in his commentary on the *Metaphysics*, he mentions his yearning for his early studies in astronomy. Ibn Rushd studied the writings of Arabic-speaking astronomers and expressed his own opinion regarding the three kinds of planetary motions: those that can be detected by the naked eye, those that can be seen by instruments of observation (remarking that some occurred over long periods of time

that exceeded the lifetime of observers), and those planetary movements whose existence can only be surmised by reasoning. Between AD 1169 and 1179, Ibn Rushd visited many places in the Almohad realm. He was actively researching matters pertaining to astronomy when he met ► [Ibn Ṭufayl](#), a philosopher and astronomer in his own right. Ibn Ṭufayl enhanced Ibn Rushd's career by introducing him to Abū Ya'qūb Yūsuf, who appointed Ibn Rushd as *qāḍī* of Seville in AD 1169. Ibn Rushd returned to Cordoba in AD 1171, at which time he was still holding the office of *qāḍī*. In AD 1182, he succeeded Ibn Ṭufayl as a personal doctor to Abū Ya'qūb Yūsuf, and was elevated to the office of grand *qāḍī* of Cordoba.

For 10 years Ibn Rushd enjoyed the patronage of Abū Ya'qūb Yūsuf. Out of jealousy, jurists (*al-fuqahā'*) of the Mālikī sect, whose influence had grown as a result of their religious zeal during the period of the Crusades, successfully conspired against him for his free-minded views. He was summoned to appear in court, and his philosophical writings were deemed contrary to the teachings of Islam. Ibn Rushd fell from grace in AD 1195 and was banished to Lucena, a province of Cordoba.

Very little is known about Ibn Rushd as a teacher of medicine. Nevertheless, the names of two of his students are known: 'Abd Allāh al-Nadrūlī and 'Isā ibn Aḥmad ibn Muḥammad ibn Qādir. The latter transcribed the whole text of Ibn Rushd's book *Al-Kullīyyāt* (Generalities) from the author's own autograph, during his lifetime, and with his approval.

Kitāb al-Kullīyyāt (Latin, *Colliget*) consists of seven books: *Tashrīḥ al-A'ḍā'* (The Anatomy of Organs), *al-Ṣiḥḥa* (Health), *al-Maraḍ* (Disease), *al-'Alāmāt* (Symptoms), *al-Adwiya wa'l-Aghdhiya* (Drugs and Foods), *Hif Ṣ-al-ṣiḥḥa* (Hygiene), and *Shifā' al-Amrāḍ* (Recovery from Disease). The purpose of the book, according to the author, is to provide medical men with an introduction to concise accounts of the different parts of medicine (*ajzā' al-ṭibb*).

Scientific collaboration existed between the eminent practitioner Ibn Zuhr (Avenzoar, d. AD 1162) and Ibn Rushd. Ibn Rushd asked Ibn Zuhr

to write a book on therapy, which he did. It was called *al-Taysīr fī'l-mudāwāt wa'l-tadbīr* (An Aid to Therapy and Regimen). *Al-Taysīr* and the *Kullīyyāt* together were meant to cover the whole science of medicine, possibly instead of Ibn Sīnā's (Avicenna, d. AD 1037) *Kitāb al-Qānūn fī'l-Ṭibb* (Canon of Medicine), which Ibn Zuhr severely criticized.

A merchant from Baghdad presented Ibn Zuhr with a beautifully transcribed and ornamented copy of Ibn Sīnā's *Kitāb al-Qānūn*. After reading it for the first time, Ibn Zuhr condemned the book and kept tearing off the margins of its leaves, which he used for jotting down prescriptions for his patients. It took almost a century before a copy of *Kitāb al-Qānūn*, completed by its author in Hamadan (Persia), actually reached Cordoba, Ibn Rushd's home town.

Ibn Sahl

Roshdi Rashed

Ibn Sahl, Abū Sa'd al-'Alā', was a first-class mathematician. From his correspondence as well as from diverse information transmitted by

the same crystal. He will not fail to give this same ratio again, nor to reproduce this same figure, each time he discusses refraction in the crystal.

This ratio is nothing but the inverse of the index of refraction in the crystal in relation to air. In fact, let us consider i_1 and i_2 , the angles formed, respectively, by CD and CE with the perpendicular GH. One has

$$\frac{1}{n} = \frac{\sin i_1}{\sin i_2} = \frac{CG}{CH} \frac{CE}{CG} = \frac{CE}{CH}.$$

Ibn Sahl takes on segment CH point I such that CI = CE, and point J at the middle of IH. One has

$$\frac{CI}{CH} = \frac{1}{n}.$$

The division CIJH henceforth characterizes the crystal for all refraction.

Ibn Sahl made innovations not only in optics, but also in mathematics. Among his mathematical inventions, I shall mention only one paper, set down as a follow-up to his contemporary, the mathematician al-Qūhī: his study of the method of projection of the sphere. Al-Qūhī is, in fact, the author of a treatise on *The Art of the Astrolabe by Demonstration*. This treatise is composed of two books, of which the first opens with an introductory chapter on the theory of projections. The propositions which al-Qūhī set forth seemed “difficult to understand” to one of his contemporaries, who turned to Ibn Sahl for clarification of the notions found therein and for the proof by synthesis of what al-Qūhī showed by analysis. We have here a situation of privileged history: we are witness to the elaboration of a new chapter of geometry by two contemporary mathematicians.

In conclusion, I remark upon the emergence of Ibn Sahl, a figure until recently almost unknown, and two chapters: anaclastics and the study of projection of the sphere. Ibn Sahl also made a substantial contribution in infinitesimal mathematics as well as in construction problems – the regular heptagon, for instance.

Ibn Sarabi (Serapion)

E. Ruth Harvey

There are two different Arab authors known to the medieval Latin west as “Serapion,” and the confusion between them in all of the authorities seems inextricable. The elder of the two authors was a Syrian, Yūḥannā ibn Sarabiyun, who lived in the ninth century. He wrote two books in Syriac, which were translated into Arabic: they are called the *Large Kunnāsh* (it was in 12 parts) and the *Small Kunnāsh* (in 7 parts). Manuscript copies of the Arabic versions exist in European libraries; what sounds like a whole copy of the *Large Kunnāsh* is in Istanbul. Both works deal with medicine and diet, but not surgery; ► [al-Rāzī](#) (Razes), who may have been a younger contemporary, cites Serapion, naming the *Kunnāsh*, and ‘Alī ibn ‘Abbās al-Majūsī (d. 994) criticizes Serapion for ignoring surgery. The *Small Kunnāsh* was translated into Latin by Gerard of Cremona (d. 1187) and entitled *Practica Joannis Serapionis dicta Breviarium*. There are many manuscript copies of this version and some early printed texts. Moses ben Mazliach translated Gerard’s version into Hebrew, and a manuscript of this translation still survives.

The younger Serapion is an even more obscure figure. He was the author of a treatise on drugs called *Kitāb al-adwiya al-mufrada*, which was translated into Latin as *Liber de medicamentis simplicibus* by Simon de Cordo of Genoa and Abraham of Tortosa in about 1290. The younger Serapion cannot have lived earlier than the eleventh century, because he cites among his authorities not only al-Rāzī, but also Ibn al-Wāfid (997–1075). There are many manuscript copies of the Latin translation, and several early prints. Usually the works of both Serapions appear together. In the Latin text, the author explains that he intends to collect and reconcile the views of Dioscorides and Galen on a wide variety of medicinal substances, and then to add in the opinions of others. In his chapter on pearls, for instance, he describes the generally accepted power of pearls to strengthen the heart; he then goes on to cite four Arab authorities on the effects of pearls on the eyesight, the blood, the nerves, melancholia, and as a dentifrice.

Ibn Sīnā (Avicenna)

Mehdi Aminrazavi

Abū ‘Alī al-ḥusain ibn ‘Abdallāh ibn Sīnā (980–1037), also known as Avicenna, was born

in the city of Būkhārā in the Eastern part of Persia into an Isma‘ili family. He demonstrated an incredible genius for learning, and having mastered the *Qu’rān* and the sciences of his time, became a physician at age 16. Ibn Sīnā gained favor with the Sāmānid dynasty for having cured Prince Nūḥ ibn Manṣūr and was thus allowed to use the royal library. He mastered other sciences such as psychology, astronomy, chemistry, and pharmacology by age 18, and toward the end of his life said he had learned everything he knew by then.

Ibn Sīnā lived in a tumultuous time when different princes were engaged in a power struggle, resulting in his traveling from city to city. He first went to Gorgān, an area close to the Caspian Sea, crossing the desert on foot, and after a while traveled to Khorāsān, Rayy, and Qazwīn, until he finally settled in Hamadān at the request of prince Shams al-Dawlah. In 1022, following the death of the prince, Ibn Sīnā went to Iṣfahān where he found the peace and serenity that the intellectual life demands. In 1037 while traveling with ‘Alā’ al-Dawlah he became ill and died as the result of colic. He is buried in Hamedan.

Ibn Sīnā gained the title of *Shaykh al-Ra’īs* (Master of the Wise) because he composed numerous treatises, 276 of which have been alluded to by his commentators. It is noteworthy that he wrote a great number of these works on horseback while fleeing from one city to another.

Ibn Sīnā’s most extensive and elaborate work is *Kitāb al-shifā’* (The Book of Healing) which itself consists of four segments: *al-Manṭiq* (Logic), *Tabī‘iyyāt* (Natural Philosophy), *Riyāḍiyyāt* (Mathematics), and *Ilāhāyyāt* (Metaphysics). To this monumental work should be added *Kitāb al-nijāt* (The Book of Deliverance), a synopsis of the *Shifā’*, and his last major work *al-Ishārāt wa’l-tanbīhāt* (The Book of Directives and Treatments). Among his other philosophical works are *‘Uyūn al-ḥikmah* (Fountain of Wisdom), *Kitāb al-hidāyah* (The Book of Guidance), *al-Mabda’ wa’l-ma’ād* (The Book of Origin and End), and the first major work written in Persian for ‘Alā’ al-Dawlah, *Dānishnāmah-yi ‘Alā’ ī* (The Book of Knowledge). Finally, there are a few works

which are mystical and visionary, such as *Ḥayy ibn Yaqẓān* (Son of the Living Awake), and *Risālat al-ṭaīr* (Treatise of the Bird).

Ibn Sīnā was a great synthesizer in that he not only incorporated the ideas of some of his predecessors such as ► [al-Kindī](#) and al-Fārābī, but also made extensive use of Greek philosophy, in particular Neoplatonism, Plato and Aristotle. From Plotinus he adopted the emanation scheme, from Plato his theory of archetypes, and from Aristotle his logic, physics, and psychology. The genius of Ibn Sīnā was in interpreting these different thoughts within the unitary matrix of Islam.

Ibn Sīnā has been called “philosopher of being” for he brought the question of being and the study of ontology to the forefront of philosophical debates and thereby corrected a deficiency that he saw in Greek philosophy, in particular in Aristotle. Ibn Sīnā divided all beings into three categories: necessary, contingent, and impossible. Furthermore, he argued that existent beings were made up of an essence and existence. This distinction became the central theme of medieval ontological discussions as well as of the subsequent debates within the Islamic philosophical tradition.

Ibn Sīnā, who had studied the Ptolemaic and Aristotelian systems, adopted the Islamic astronomical view based on the nine spheres and interpreted them within the scheme of the emanation of intellects. Each order of intellect accordingly corresponds to one of the heavens. For example, the second intellect corresponds to the highest heaven which is located above the fixed stars, and the tenth intellect corresponds to the moon below which the corporeal domain of our world is located.

Medicine

Ibn Sīnā was in the tradition of such grand Muslim physicians as ► [al-Rāzī](#) and al-Majūsī. By the age of 20, he had already become an accomplished physician and gained the respect of the court for having cured several members of the royal family. Eventually he came to be known as

the “prince of physicians”. He is the author of the *Qānūn al-ṭibb* (The Canon of Medicine), which became a standard text both in the Christian West and the Islamic world. In addition to his *magnum opus*, Ibn Sīnā wrote a number of treatises on medicine both in Arabic and Persian some of which deal with particular diseases. He also wrote a book in which principles of medicine are written as poetry in order to facilitate their memorization by medical students.

In medicine, Ibn Sīnā was in many ways a follower of Greek ideas on medicine. However, he made the following revisions:

1. Unified the central principles of Greek medicine and interpreted them within an Islamic framework.
2. Made the theoretical and practical aspects of medicine represent a unified whole.
3. Documented the effects of medications on the body and commented on the necessity of a methodology in the study of pharmacological issues.
4. Introduced a number of medications and treatments for illnesses unknown to Greeks.

Ibn Sīnā believed that the science of medicine was divided into two categories, theoretical and practical. Illnesses were brought about either by internal or external causes. Internal illnesses were caused by an imbalance of temperament in the human body. These causes could also be the result of psychological elements.

Ibn Sīnā is known to have prescribed a variety of treatments for ailments, ranging from psychotherapy and diet to exercising. In the first volume of the *Canon of Medicine*, he states that medicine is the science of knowing the structure of the human body, and he goes on to discuss the fundamental principles necessary to maintain human health. He discusses surgery as an independent branch of medicine and elaborates on the science of anatomy. In the second volume, Ibn Sīnā explains various healing properties of simple and compound drugs and their various applications. In the third and fourth volumes, he presents his diagnosis of a variety of illnesses known to him, ranging from meningitis and cancer to

tuberculosis and gastrointestinal illnesses. In the fifth volume of this work, Ibn Sīnā offers an extensive discussion of pharmacology, providing a detailed description of the effects of medications on body.

Some of his observations are extraordinarily advanced for his time. For example, he attributed the cause of plague to mice, commented on a number of contagious diseases, used single hair lines of horses for stitching after surgery, experimented with various drugs as anesthetics when operating on patients, described surgical processes for many operations such as gall bladder, used spices to stop bleeding after surgery, and understood the relationship between temperature and the spread of diseases. He even experimented on animals using different drugs.

Ibn Sīnā's treatment of the subject of psychology as a science which is both independent and part of the field of medicine is extensive. He first argues for the existence of a soul which is rather similar to the Aristotelian *psyche* and then shows how this incorporeal part of man interacts with his corporeal dimension. Ibn Sīnā then goes on to say that the health of the body to a large extent depends on the health of the soul and he offers much elaboration on that point throughout his works.

Perhaps one of the most important contributions of Ibn Sīnā to the field of medicine is the technical medical terminology which he introduced and which is still used by physicians in the Islamic countries.

Psychology

In *The Book of Healing*, Ibn Sīnā treats the subject of the "three kingdoms" (minerals, plants, and animals). He extends the hierarchy of the incorporeal world to the material world, concluding that whereas each domain has its soul it is only in humans that these souls reach their completeness. Ibn Sīnā's treatment of the human soul, its relationship with the body and the active intellect, is extensive. He introduces

five internal senses and their equivalent five external senses.

The scope of Ibn Sīnā's writings on sciences includes such topics as motion, the process of sedimentation, and classification of minerals in the *Shifā'*, which came to be known in the West as *De mineralibus*. In a famous debate with ► [al-Bīrūnī](#), Ibn Sīnā responded to ten questions on Aristotle's *De Caelo* and eight other questions such as how vision is possible, the relationship between water and light, the nature of a vacuum, heat, cooling, and how it is that ice floats on water.

Ibn Sīnā's philosophy remained the dominant philosophical school in the medieval west where he became known through translations of his works in Islamic Spain by Avendeuth, who was a Jewish philosopher and Gerard of Cremona. The Sicillian school also benefited much from Ibn Sīnā who was translated by Michael Scot. Ibn Sīnā's works continued to be translated through the sixteenth century influencing such western philosophers as the Augustinian Gundisalvo, Albertus Magnus, William of Auvergne, Alexander of Hales, Roger Bacon, and Duns Scotus.

Ibn Sīnā left an indelible mark on the history of science, medicine, and philosophy.

Ibn ʿTāwūs

Zeina Matar

Raḍī al-Dīn Abū-l-Qāsim 'Alī ibn Mūsā ibn Ja'far ibn Muḥammad ibn Aḥmad ibn Muḥammad ibn ʿTāwūs was a religious scholar, historian, and astrologer. He was born in al-ḥilla (Iraq) on 15 Muḥarram 589/21 January 1193. He belonged to a distinguished family of scholars, the Banū ʿTāwūs, whose ancestry can be traced back to 'Alī ibn Abī Ṭālib.

Ibn ʿTāwūs grew up in the town of al-ḥilla, which had been established by the famous scholar Abū Ja'far al-Ṭūsī (385–458/995–1066) as a center of learning boasting five *madrasas* (institutions for the study of the Islamic sciences). Ibn ʿTāwūs spent his formative years in his native town, and in Baghdad where he lived for 15 years. He made pilgrimages to the holy Shīʿī shrines of Najaf, Kerbela, and al-Kazimayan. He had a reputation for saintly powers, and concerned himself extensively with popular religious practices.

Ibn ʿTāwūs concentrated mainly on devotional literature, but he also wrote in the fields of history and astrology (see the listing of primary sources in the bibliography). In AH 650/AD 1252, he owned over 1,500 volumes in his private library. Professor E. Kohlberg of the Hebrew University of Jerusalem has contributed a superb reconstruction of this library and a detailed critical analysis of the works it contained.

Ibn ʿTāwūs was one of the most prolific medieval Shīʿī scholars, who aimed at providing the believer with a set of guiding moral and ethical principles. The sources stress his “erudition, knowledge, asceticism, devoutness, trustworthiness, understanding of *fiqh* (science, or knowledge), loftiness and godfearingness [along with his talents as] poet, man of letters, writer, and eloquent speaker” (Āghā Buzurg Tihirānī 1983). A man of deep faith, concerned with religious matters, Ibn ʿTāwūs could also display wisdom

in sensitive political situations, as in this apocryphal story:

When Sultan Hulagu conquered Baghdad in 656/1258, he ordered that the scholars give an opinion on which was preferable: the unbelieving but just sultan, or the Muslim despotic one. The scholars were then gathered in al-Mustaṣiriyya for this purpose. They refrained from answering. Raḡī al-Dīn ‘Alī Ibn Ṭāwūs was present at this Council. When he saw their hesitation, he took the *fatwa* (fatwa, legal opinion), and wrote that the unbelieving but just ruler was preferable to a Muslim despot.

Although Ibn Ṭāwūs declined the office of Naqābat al-Ashrāf under the Caliph al-Mustaṣir (d. 640/1242), he apparently changed his mind during the Mongol Period, and received the title from ► [Naṣīr al-Dīn al-Ṭūsī](#) (d. 672/1273). This important office, which had originated under the Buwayhids (also Buyids, a dynasty in Persia and Iraq, 320–454/932–1062), enabled the Sayyid families to represent their community in political, religious, and scholarly matters.

The date on which Ibn Ṭāwūs died in Baghdad is generally accepted as 5 Dhū-l-qa ‘da 664/9 August 1266, and he was probably buried in Najaf.

Ibn Tibbon

Emilia Calvo

Ibn Tibbon, Jacob Ben Machir, is known as Profeit in Romance languages and as Prophatius Judaeus in Latin. These names come from the translation of *mehir* (prophet) into the languages of Southern France.

Ibn Tibbon was probably born in Marseille ca. 1236. His family was originally from Granada and, for four generations, had been devoted to the translation of Arabic religious, philosophical, and scientific texts. Through these translations, Arabic learning and therefore Greek scientific traditions were made available to the scholars of medieval Europe. Ibn Tibbon studied medicine at Montpellier and probably lived in Gerona, Spain between AD 1266 and 1267. He spent most of his life in Lunel, where his great-grandfather had established and practiced medicine at the beginning of the twelfth century, and Montpellier where he died in AD 1305.

Ibn Tibbon translated works by Autolycus of Pitane, Euclid, Menelaus of Alexandria, Qusṭā ibn Luqa, Ibn al-Haytham, Ibn al-Ṣaff īr, ► [Ibn al-Zarqāllu](#), al-Ghazālī, ► [Jābir ibn Aflaḥ](#), and Ibn Rushd from Arabic into Hebrew.

He is also the author of some works dealing with astronomy:

Roba ‘Yisrael (Quadrant of Israel), written between AD 1288 and 1293, in which an astronomical instrument, called the *quadrans novus*, is described. It consists of a simplification of the face of the astrolabe. Some examples of this instrument have been preserved.

The *Almanac*, calculated for Montpellier and dated 1 March 1300. It is based on Ibn al-Zarqāllu's reelaboration of Awmātiyūs' almanac, although the author says that he has used the Toledan Tables, which is incorrect.

Ibn Tibbon is also the author of the Prologue to Abraham bar Hiyya's *Sefer Hesbon Mahleket ha-Kokabim* (Calculation of the Courses of the Stars).

Ibn Ṭufayl

E. Ruth Harvey

Abū Bakr Muḥammad ibn 'Abd al-Malik ibn Muḥammad ibn Muḥammad ibn Ṭufayl al-Qaisi was an Arab physician famous for his encyclopedic learning. He was born at Guadix in Granada (modern Spain) in the first decade of the twelfth century. He served local rulers as physician and diplomat, and eventually became the court physician to Abū Ya'qūb Yūsuf, the Almohad prince who became the most powerful Muslim ruler of his day. Ibn Ṭufayl enjoyed a close friendship with Abū Ya'qūb until the latter's death in 1184; he was esteemed and cherished

by Abū Ya'qūb's successor, Abū Yūsuf Ya'qūb, until his own death in 1185–1186.

Ibn Ṭufayl's importance for history is twofold: the influence of his unique work, *Ḥayy ibn Yaqzān*, and his patronage of one of the most important Muslim philosophers of the Middle Ages, Ibn Rushd (known to the west as Averroes). The medieval Arab historian, 'Abd al-Wāḥid al-Marrākushi, recorded that Ibn Ṭufayl would bring all sorts of learned men to his sovereign's notice. It was in this way that Ibn Rushd was given audience with Abū Ya'qūb Yūsuf, and there was led on by the praise and encouragement of Ibn Ṭufayl to demonstrate his familiarity with Aristotelian philosophical traditions. The Sultan himself joined in the discussion, and Ibn Rushd was commissioned to compose his great commentaries. It was through the mediation of Ibn Rushd's works that Aristotle was reintroduced to the Latin West. The astronomer al-Bītrūjī (known in the West as Alpetragius) was a disciple and friend of Ibn Ṭufayl; he mentions Ibn Ṭufayl's criticisms of the traditional astronomical theories on epicycles and eccentrics.

Ibn Ṭufayl was said to have written poetry as well as works on medicine and astronomy, but nothing seems to survive except *Ḥayy ibn Yaqzān* and (possibly) a poem on medicine recently rediscovered (see Russell, 1986). The highly unusual *Ḥayy ibn Yaqzān* (Life, Son of Awareness) is a philosophical tale in the form of a table: it tells how Ḥayy, cast up as a baby or spontaneously generated on an island, is fostered by a doe and grows to adulthood without any human contact whatsoever. Ibn Ṭufayl's interest lies in positing the natural unfolding of the human reason from the blank of infancy to the highest possible intellectual development; Ḥayy reaches the summit of human possibility in a mystical experience of the godhead. Eventually Ḥayy meets another human being who is so filled with awe at Ḥayy's intellectual and spiritual attainments that he persuades him to make an attempt to convert human society to wisdom. Humanity proves to be unworthy of Ḥayy's teaching, and Ḥayy and his new-found friend retreat back to the island again to spend the rest of their lives in contemplation.

Ḥayy ibn Yaqzān draws on the philosophy of Ibn Sīnā. It was edited as early as 1671 by Edward Pocock, who provided a Latin translation, thus inserting Ibn Ṭufayl's ideas into the mainstream of European culture. The *Philosophus Autodidactus*, as Pocock named it, was sent to Huygens, Locke, and Leibniz; it was possibly an influence on Defoe's *Robinson Crusoe*, and almost certainly one on Rousseau's *Emile*. English translations have been appearing since 1686; there are Dutch, German, French, Catalan, Hebrew, Persian, and Russian versions. It is still stirring up scholarly debate and controversy.

Ibn Wāfid

Emilia Calvo

Ibn Wāfid Abū'l-Muṭarrif 'Abd al-Raḥmān ibn Muḥammad was a pharmacologist and physicist who lived and worked in Toledo during the first half of the eleventh century (ca. 1008–1075). He studied the works of Aristotle, Dioscorides, and Galen in Cordoba but then he moved to Toledo where he planted a botanical garden for the king of this city, al-Ma'mūn.

Ibn Wāfid is the author of a book entitled *Kitāb fī-l-adwīya al-mufrada* (Book on the Simple Medicines) which is a synthesis of Dioscorides and Galen. It is an extensive work to which the author devoted 20 years. It was abridged and translated into Latin by Gerard of Cremona. Translations into Catalan and Hebrew are also extant.

Ibn Wāfid is also the author of a pharmacopeia and manual of therapeutics entitled *Kitāb al-wisād fī 'l-ṭibb* (Book of the Pillow on Medicine) which, according to Juan Vernet, could be a misreading of the Arabic title *Kitāb al-rashshād fī 'l-ṭibb* (Guide to Medicine). This work can be considered complementary to the preceding one because Ibn Wāfid describes compound medicines in it, and it is a practical book: the information given is based on experience. Ibn Abī Uṣaybi 'a attributes to Ibn Wāfid a work entitled *Mujarrabāt fī-l-ṭibb* (Medical Experiences) which could probably be identified with this Book of the Pillow.

Ibn Wāfid is also the author of two works entitled *Tadqīq al-naẓar fī 'ilal Ḥāssat al-baṣar* (Observations on the Treatment of Illness of the Eyes) and *Kitāb al-Mughīth* (Book on Assistance) which are not preserved, and of a treatise

on balneology which is preserved in a Latin version entitled *De balneis sermo* (Venice, 1553).

Ibn al-Abbār attributes to Ibn Wāfid a book entitled *Majmuʿ al-Filāḥa* (Compendium of Agriculture) although his authorship is now being questioned.

Ibn Yūnus

David A. King
Frankfurt University, Frankfurt am Main,
Germany

Ibn Yūnus, Abu'l-ḥasan 'Alī ibn 'Abd al-Raḥmān ibn Aḥmad ibn Yūnus al-Ṣadafī was one of the greatest astronomers of medieval Islam. Unfortunately, nothing of consequence is known about his early life or education. As a young man, he witnessed the Fatimid conquest of Egypt and the founding of Cairo in 969. In the period up to the reign of Caliph al-Azīz (975–996), he made astronomical observations that were renewed by order of the Caliph al-ḥākim, who succeeded al-Azīz in 996 at the age of eleven and was much interested in astrology. Ibn Yūnus' recorded observations continued until 1003.

Ibn Yūnus' major work was a monumental *zīj* or astronomical handbook with tables. The *Ḥākimī Zīj*, dedicated to the Caliph, is

distinguished from all other extant *zīj*es by beginning with a list of observations made by Ibn Yūnus and others made by some of his predecessors. Despite his critical attitude toward these earlier scholars and his careful recording of their observations and some of his own, he completely neglects to describe the observations that he used in establishing his own planetary parameters – nor does he indicate whether he used any instruments for these observations. Indeed, the *Ḥākimī Zīj* is a poor source of information about the instruments he used. In view of the paucity of this information, it is remarkable that the statement that Ibn Yūnus worked in a “well-equipped observatory” is often found in popular accounts of Islamic astronomy. Sayili has shown how this notion gained acceptance in Western literature.

Ibn Yūnus' *Zīj* was intended to replace the *Mumtaḥan Zīj* of Yaḥyā ibn Abī Mansūr, prepared for the Abbasid Caliph al-Ma'mūn in Baghdad almost 200 years earlier. When reporting his own observations, Ibn Yūnus often compared what he observed with what he had computed using the *Mumtaḥan* tables.

The observations he described are of conjunctions of planets with each other and with Regulus, solar and lunar eclipses, and equinoxes; he also records measurements of the obliquity of the ecliptic (Chap. 11) and of the maximum lunar latitude (Chap. 38).

In spherical astronomy (Chaps. 12–54), Ibn Yūnus reached a very high level of sophistication. Although none of the several hundred formulae that he presents is explained, it seems probable that most of them were derived by means of orthogonal projections and analemma constructions, rather than by the application of the rules of spherical trigonometry that were being developed by Muslim scholars in Iraq and Iran.

The chapters of the *Zīj* dealing with astrological calculations (77–81), although partially extant in the anonymous abridgment of the work, have never been studied. Ibn Yūnus was famous as an astrologer and, according to his biographers, devoted much time to making astrological predictions.

Ibn Yūnus' second major work was part of the corpus of spherical astronomical tables for time-keeping used in Cairo until the nineteenth century. It is difficult to ascertain precisely how many tables in this corpus were actually computed by Ibn Yūnus. Some appear to have been added in the thirteenth and fourteenth centuries. The corpus exists in numerous manuscript sources, each containing different arrangements of the tables or only selected sets of tables. In its entirety, the corpus consists of about 200 pages of tables, most of which contain 180 entries each. The tables are generally rather accurately computed and are all based on Ibn Yūnus' values of $30^{\circ}0'$ for the latitude of Cairo and $23^{\circ}35'$ for the obliquity of the ecliptic. The main tables in the corpus display the time since sunrise, the time remaining to midday, and the solar azimuth as functions of the solar altitude and solar longitude. Entries are tabulated for each degree of both arguments, and each of the three sets contains over 10,000 entries. The remaining tables in the corpus are of spherical astronomical functions, some of which relate to the determination of the five daily prayers of Islam. The impressive developments in astronomical timekeeping in fourteenth-century Syria, particularly the tables of al-Khalīlī for Damascus, also owe their inspiration to the main Cairo corpus.

It is clear from a contemporary biography of Ibn Yūnus that he was an eccentric, careless, and absent-minded man who dressed shabbily and had a comic appearance. One day in the year 1009, when he was in good health, he predicted his own death in 7 days. He attended to his personal business, locked himself in his house, and washed the ink off his manuscripts. He then recited the *Qur'ān* until he died – on the day he had predicted. According to his biographer, Ibn Yūnus' son was so stupid that he sold his father's papers by the pound in the soap market.

Ibn Ṣuhr

Munawar Ahmad Anees

Abū Marwān 'Abd al-Mālīk ibn Ṣuhr (Latin: Avenzoar; 484–557/1092–1162) belonged to the

Arabian tribe of Iyād, Banū Zuh̄r. His father, Abū al-ʿAlā ibn Zuh̄r (d. 525/1131), was a respected physician in the courts of the Murābiṭ dynasty (482–541/1090–1147). He trained his son in the art and craft of medicine.

Like his father, Ibn Zuh̄r started his career in the service of the Murābiṭ dynasty and earned a good reputation. During the reign of ʿAlī ibn Tashfīn (499–537/1106–1143), he served at the palace in Marrakesh, Morocco, where his life was full of trials and tribulations. In ca. 535/1141, he was stripped of his official position and imprisoned. Although he was pardoned and released, he endured a hard life in prison and the experience left a resentment in his heart against the ruling dynasty.

The beginning of the reign of al-Muwāḥḥidūn proved to be a blessing for Ibn Zuh̄r. He was not only appointed as an official physician but also became a *wazīr* in the court of Abū Muḥammad ʿAbd al-Mūmin (d. 558/1163). During this period, Ibn Zuh̄r transmitted his knowledge and skills to his children with meticulous attention. His son and daughter both became famous physicians. One of Ibn Zuh̄r's treatises, *al-Tadhkirah* (The Remembrance), was dedicated to his son in appreciation of his achievements.

At least nine of Ibn Zuh̄r's works are known, but only a few are extant. He is said to have written two works and dedicated them to ʿAbd al-Mūmin. *Al-Aghdhīyyah* (On Dietetics) is a text on the therapeutic properties of selected foods. *Al-Tiryāq al-Sabʿīnī* is a book of antidotes against poisoning by enemies. This work, perhaps, was Ibn Zuh̄r's way of expressing gratitude to his benevolent patron.

Al-Taysīr fī al-Mudāwāt wa al-Tadbīr (On Preventive Regimen and Treatment), in 30 treatises, is considered to be his monumental work. His friend Ibn Rushd considered it a great source of medical knowledge and therapeutic advice. In its Latin version, *Alteisir scilicet regiminis et medelae*, the treatise remained in wide circulation across Europe for centuries. Both Arabic and Latin copies of this work are extant. True to the medical norms of his days, Ibn Zuh̄r presented in this work a mix of astrology and folklore blended with therapeutics and

pharmacology. *Al-Kulliyāt* (The Collection), a general compilation on medical practice, appears as an appendix.

The great historiographer Ibn Abi ʿUṣaybiʿah, in his encyclopedic work *ʿUyūn al-Anbā fī Ṭabaqāt al-Aʿibbā*, listed only seven of Ibn Zuh̄r's works:

1. *Fī al-Zīnah* (On Beautification)
2. *Al-Tiryāq al-Sabʿīnī* (On Antidotes)
3. *Fī ʿIlāl al-Kilā* (On Diseases of the Kidney)
4. *Fī ʿIllat al-Baraṣ wa al-Bahaq* (On Leprosy and Vitiligo)
5. *Al-Aghdhīyyah* (On Dietetics)
6. *Al-Tadhkirah* (The Remembrance)
7. *Al-Taysīr fī al-Mudāwāt wa al-Tadbīr* (On Preventive Regimen and Treatment)

He does not mention two of his treatises. One of the missing ones is *Al-Iqtisād fī Iṣlāḥ al-Anfūs wa al-Ajsād* (Treatment and Healing of the Soul and Body). Addressed to the general reader, it focuses on problems of hygiene and therapeutics. The second is *Jāmiʿ al-Asrār al-Ṭibb* (Compendium of Medical Wisdom). In addition to a discussion on dietetics, this work describes the physiology of several organs including the spleen, liver, and bladder.

Ibn Zuh̄r was a prolific writer and a highly successful medical practitioner. Some of his work showed the influence of the Hippocratic and Galenic traditions, but his original insights came from a rich family heritage in medical practice. Thus, going against the Greco-Roman medical dictates, Ibn Zuh̄r engaged in experimental work and recorded his observations. His detailed study of the pericardial abscess, pharyngeal paralysis, intestinal and mediastinal tumors, and inflammation of the middle ear were great improvements over the work of his predecessors.

Ibn Zuh̄r was one of the great Muslim clinicians and therapists. Through numerous translations of his works, he remained highly influential in the medical academies of the West. In his later age, he suffered from a malignant tumor that ultimately caused his death. He was buried in Seville, Spain.

Ibrāhīm Ibn Sinān

Roshdi Rashed

Ibrāhīm Ibn ► [Sinān Ibn Thābit](#) Ibn Qurra was born in Baghdad in 296/909 where he died 37 years later in 335/946. Grandson of the famous mathematician Thābit Ibn Qurra, cousin of the

famous literary figure Hilāl al-Ṣābi', son of a great physician and mathematician Sinān Ibn Thābit, he thus belonged to an intellectual aristocracy whose members frequented the corridors of power and the upper levels of the worlds of science and medicine. Ibrāhīm was born into and raised in this world, before being the object of a short-lived persecution to which he makes allusion but explains neither the cause nor the duration. Ibrāhīm Ibn Sinān was not only the "heir" to great tradition, but also a mathematician of genius in his own right who made his own mark on the mathematics of his era.

Ibrāhīm Ibn Sinān was also heir to a historical tradition. He belonged to a privileged generation, the fourth since the ► [Banū Mūsā](#). The translation of the major mathematical texts had been essentially completed and the great traditions of research had already been well established: that of the algebraists, beginning with ► [al-Khwārizmī](#) and extended by ► [Abū Kāmil](#); that of the geometers, ► [al-Jawharī](#), ► [al-Nayrīzī](#), etc., who followed the work of Euclid; and the tradition of the Banū Mūsā which, thanks to mathematicians like Thābit Ibn Qurra, had already gathered considerable results, developed new methods, and elaborated theories. Ibrāhīm Ibn Sinān was clearly a part of this tradition in which Archimedean geometry, a geometry of measurement, and the geometry of Apollonius, which was concerned with the properties of positions, were all combined. Profiting from scholarly works, especially those of his grandfather Thābit Ibn Qurra, Ibrāhīm Ibn Sinān developed the study of geometric transformations and their applications to conic sections, as well as to the measurement of the area of a portion of a parabola. He extended their work on sundials in developing a theory of a whole class of instruments. Finally the questions posed by his predecessors about analysis and synthesis prompted him to write the first treatise worthy of the name on the subject.

Ibrāhīm Ibn Sinān explained the composition of his work in his own autobiography which happily still exists. He published the autobiography after his 25th year, in 934. According to his own account, he began his research at age 15; at 16 or 17 he had written a first version of his book

Fī Alāt al-aẓlāl (On Instruments of Shadows), which he revised at the age of 25. A year later he was discussing and criticizing Ptolemy's views on The Determination of the Anomalies of Saturn, Mars, and Jupiter (*Fī istikhrāj ikhtilāfāt Zuḥal wa al-Mirrīkh wa al-Mushtarī*) in a treatise that he completed 6 years later, at the age of 24. In geometry, Ibn Sinān wrote *Fī al-dawā'ir al-mutamāssa* (The Tangent Circles), *al-Taḥlīl wa'l-Tarkīb* (Analysis and Synthesis), *Fī al-masa'īl al-mukhtāra* (Selected Problems), *Fī misāḥat qif' al-maḥrūt al-mukāfī* (The Measurement of the Parabola), and the *Fī rasm al-quṭū 'althalātha* (Drawing of the Three Conic Sections). All these works had been published and revised before Ibn Sinān was 25.

To illustrate the approach of Ibn Sinān let us look briefly at his *Measurement of the Parabola*, beginning with what he wrote about his own studies:

My grandfather had determined the measurement of this section. But several contemporary geometers led me to understand that a work of ► *al-Māhānī* on the same subject, which they presented to me, was easier than my grandfather's. I was not pleased that al-Māhānī's work was more advanced than my grandfather's without there being one among us who surpassed his work. My grandfather had determined his result in twenty propositions. He proceeded from several arithmetic lemmas included in the twenty propositions. The question of the measurement of the section appeared to him clearly through the method of *reductio ad absurdum*. Al-Māhānī also proceeded from arithmetic lemmas. He then demonstrated his demand by the method of *reductio ad absurdum* in five or six propositions, which involved lengthy discussions. I myself then determined the measurement in three geometric propositions without recourse to any arithmetic lemma. I demonstrated the surface area of this same section using the method of direct proof, and I did not need the method of *reductio ad absurdum*.

In addition to expressing pride in his heritage and the certainty of an exceptional scholar, these remarks also reflect the qualities of Ibn Sinān as a mathematician: brevity, ease, and elegance.

Ibn Sinān's approach is the following: in a first proposition, he demonstrates that the affine transformation conserves the ratios of the areas in the

case of triangles and polygons; he then demonstrates in a second proposition that it is the same for the ratio of the area of a portion of a parabola to that of an associated triangle.

Ibn Sinān again had recourse to geometric transformations in his *Drawing of the Three Conic Sections*. In this treatise, he constructed an ellipse by transforming the circle by an orthogonal affinity – a process already found in the works of the ► *Banū Mūsā*. It was also by means of an affinity that he deduced all the hyperbolas of a particular hyperbola for which the latus rectum is equal to the transverse axis.

The intensity of mathematical activity, the large amount of work done, the new demands of brevity, elegance, and rigor in demonstration, as well as the general interest in geometric transformations, all led Ibn Sinān to take up the theory of analysis and synthesis again. Thus he published the first treatise devoted to this subject. He wrote "I found that the geometers of this time had neglected Apollonius's method of analysis and synthesis, as was the case for the majority of things I brought up, and that they had limited themselves just to analysis, limiting themselves to such a degree that they led analysis to the point of letting people think that this analysis was not the synthesis that they were doing."

In this treatise, Ibn Sinān undertook two tasks at once: one didactic, the other logical. On the one hand, he proposed a method (*Ṭarīq*) for geometry students which allowed them to solve geometry problems; on the other hand, he reflected on geometric analysis itself, proposing a classification of geometry problems according to their numbers and the hypothesis that they are to verify, and explaining for each class of problems the respective parts of analysis and synthesis.

There is not enough space here to take up, even very briefly, the works of Ibn Sinān. But the examples discussed above do show how this eminent geometer left his mark on all the fields in which he worked, including mathematics and philosophy. The import of his work can be discovered in the work of Ibn al-Haytham who followed up on the research of Ibn Sinān in his own treatise on analysis and synthesis and in his writings on sundials.

Ikhwān al-Ṣafā'

Gregg De Young

The American University in Cairo, Cairo, Egypt

The 48 treatises composed by the Ikhwān al-Ṣafā' (Brethren of Purity) constitute an encyclopedia of the sciences which has had a long and influential career in Islamic civilization. The collection was prepared by a group of scholars who preferred

anonymity. This anonymity has generated considerable debate among historians over their identity. Current scholarship places the date of composition in the last half of the fourth AH/AD tenth century and the place of composition in Basra. This collection of treatises continues to play an important role in the intellectual milieu of modern Islam, especially among groups influenced by Shī'ite and Ismā'īlī ideas.

The treatises contain a strong gnostic element, an emphasis on esoteric knowledge that exists within the exoteric or phenomenal features of everyday life but is accessible only to the initiated. This interest in esoteric or inner knowledge does not imply that they were uninterested in the physical world. It is necessary to have a thorough understanding of nature in order to penetrate to the inner truth that it expresses. An appreciation of nature, therefore, is one of the first steps toward union with the Divine Knowledge.

Their gnostic orientation can be seen in the classification of knowledge proposed by the Ikhwān. The student begins with introductory or preparatory (*riyāḍiyy*) topics, advances to religious (*shar'īyy*) sciences, and finally reaches the highest or philosophic (*falsafīyy*) sciences. This system is at odds with traditional Islamic discussions of the arrangement of the sciences in that it seems to make religious sciences subordinate to philosophical or intellectual sciences. In the organization of their treatise, the Ikhwān begin with mathematical sciences and advance to physical sciences, human sciences, and finally metaphysical and revealed sciences.

The gnostic tendencies of the authors also appear in the Neo-Platonic and Neo-Pythagorean descriptions of cosmogony and cosmology embedded within these treatises. God created the universe through a series of emanations from himself. First to appear was Intellect, followed by its Archetypes and the World Soul. (Intellect, the Ikhwān tell us, instructs the World Soul through the Archetypes.) The World Soul, through further emanations, produces individual souls or faculties that individuate, or give form to, prime matter. The first of these individuating emanations were the nine celestial spheres (the invisible *primum mobile*, the sphere of the

fixed stars, and the spheres of the seven naked-eye planets: Saturn, Jupiter, Mars, Sun, Venus, Mercury, and the Moon), followed by the four terrestrial elements (fire, air, water, and earth). This represents the farthest separation of soul from God. Drawn by an irresistible desire for union with the unity of God, it commences a return ascent heavenward through a process of purification from the contamination of matter achieved through personal morality and deepening esoteric knowledge of the One.

The treatises contain little mathematical or scientific information that is new. The treatise on geometry (the second treatise of the collection) reports a few simple results from Euclid: the sum of the interior angles of the triangle is two right angles, an exterior angle is equal to the two opposite interior angles, etc. However, there is no discussion of the demonstrations that validate these facts. Rather, the Ikhwān are interested in facts only when related to other facts so as to provide insight into the deeper, esoteric, meanings of mathematical knowledge. Thus, they discuss the relation between sensory and intellectual geometry. This is followed by a discussion of magic squares (numbers placed in geometric arrays) and their almost magical usefulness as talismans. Interspersed with these discussions are meditations on the usefulness of intellectual geometry (because, as abstracted from the sensations, it exercises the soul to move beyond sensory phenomena toward the invisible reality) and on the necessity for human cooperation and brotherhood in the effort.

Astronomy (including astrology) is discussed primarily in epistles 3, 16, and 36. These discussions summarize the basics of Ptolemaic cosmography as a propaedeutic to historical astrology – the idea that historical cycles mirror the cycles of the planets through the heavens. Although the authors include some basic scientific information about the heavens, such as the sizes of the planetary spheres, along with some ideas from Aristotelian physics to describe their motions, it seems their primary interest lies in the hidden meaning of this information or astrology.

Although the treatises provide little insight into the state of intellectual activity in the

sciences, they give an intriguing glimpse of what the educated nonscientist knew about the results of scientific research as they existed in that time. As such, they offer a window into what might be called a subscientific culture, a culture aware of some of the results of science and mathematics but adapting these results for nonscientific (in this case, largely social and religious) purposes.

Indigo in Bengal

Indrajit Ray

Department of Commerce, University of North Bengal (on lien), Darjeeling, West Bengal, India
Cooch Behar Panchanan Barma University,
Cooch Behar, West Bengal, India

India was the home of tropical indigo. In the Middle Ages, its international market was catered to from western and northern India through the trading network of the Armenian and Muslim communities in the main, and to a lesser extent, through the Portuguese traders and the Dutch. Its Gangetic belt, including Bengal, cultivated the crop for domestic industrial use – for example, as a dye for cotton textiles that had become universal since the days of antiquity. The global scenario, however, began to change rapidly from the late seventeenth century when the European countries – especially Spain and France, and later on, England – started plantations in their respective American colonies. Indeed, the indigo technology that was developed in America under European initiatives was altogether different from what prevailed in India. The new technology subsequently arrived in Bengal when two West Indian planters, both French by nationality, opened up an indigo factory in 1772 near Chandannagar, which was then under French possession. A series of ventures followed, capable of competing internationally. Within a short span of time, Bengal could again invade the global market using the new technology, and it was able to recover India's glory. Its export evidently rose up from 1,200 maunds (1 maund = 37 kg.) in 1783 to 39,000 maunds in 1800 as against about 12,000 maunds and 14,000 maunds, respectively, from other countries. In 1815–1816, it supplied about

128,000 maunds leaving only a small market for Mexico. In 1831, there were about 830 indigo concerns in Bengal working with 518,000 bighas of land (1 bigha = 1,600 square yards). They generated about 407,000 direct jobs in factories and 518,000 indirect jobs in agriculture.

Though the indigo dye industry developed rapidly in Bengal using foreign technology, the indigenous technology was not altogether lost in the local society. It was widely used for the dying needs of the cotton textile industry. For topical interest, therefore, both technologies are discussed here. We discuss first the plantation aspects of this dye and then deliberate on how it was processed under indigenous and foreign technologies. In view of the latter's importance, it is discussed at length.

Planting of Indigo

There were two types of indigo sowing in lower Bengal: wet (*cheetānee*) sowing and dry (or cultivated) sowing. The former took place in islands (*churs*) and other muddy stretches along the rivers, where alluvia were richly deposited. Sowers scattered their seeds over land in February, usually carrying long bamboo sticks to negotiate the mud – which was often waist or neck deep – and a cane-made basket of seeds (Fig. 1). A head servant of the factory (*āmun*) accompanied them in a small boat (*panchorey* or *dinghy*) to replenish seeds from time to time and to supervise their jobs. Where the mud deposits were deep, the sowers sailed through on a raft of three plantain-tree stems, fastened together, carrying a spirally bound cane basket which could float on the water. When the seeds were thus sown, they sunk 2–3 in. according to their own weights and sprang up in about a week. After the heavy rains during June–July, the plants grew luxuriantly and became fit for harvesting. This cultivation was least expensive, save in weeding, but highly productive insofar as the content of dye was concerned.

The cultivated sowing, i.e., sowing by tillage, took place in October. Thanks to the alluvial soils in lower Bengal, there was neither any need for

Indigo in Bengal, Fig. 1 The *cheetānee* sowing (Source: Reid, The culture and manufacture of indigo)

drilling before the plow, nor for any use of the roller afterward. Every plowing was, however, followed by dragging of a *moi* (made of a large bamboo frame) over it to pulverize the clods. When the soils were thus ready after several plowings, the seeds were broadcast, the *moi* was applied for the last time, and the land was left for the plants to grow. Once they emerged, the field required continuous weeding so that the plants got adequate nutrition. They became ripe and fit for harvesting by about the end of June when flowers began to blossom.

Plants were cut leaving the stalks (i.e., where there were no green or yellow leaves) so that there were further buds and shoots for a second, or even a third, cutting. After harvesting, however, they were carted as soon as possible to the vats since fresh leaves provided a higher productivity.

Processing Under Indigenous Technology

The main raw materials in this process were indigo plants, alkaline ley, and *chākunda* seeds (*Cassia Tora* W.). To prepare the alkaline ley,

a dyer took a given amount (say 20 sers, 1 ser = 0.933105 kg.) of fresh burned roots and stems of the plantain tree. Those were put into a large earthen pot that had a hole in the bottom with a filter of grass over it. Through the filter the dryer slowly poured 60 sers of water, which tuned out as alkaline ley. Another solution was prepared by boiling 1½ sers of *chākunda* seeds in 5 sers of water. Indigo plants were also broken into small pieces so that all the raw materials were readily available when the processing commenced.

There were four stages of processing in the indigenous technology. In the first stage, the dryer took about 60 sers of alkaline ley and five sers of indigo plants together in an earthen tub or vat and stirred them for about 3 h. Those were then equally divided into two pots. In the second stage, half of the *chākunda* solution, prepared earlier, was poured into each of those pots and boiled on a *chulā* (a native furnace) throughout the night. The third stage started the next morning when the decoction was stirred with a stick for about 1½ h. These boiling and stirring processes were repeated for four consecutive nights and mornings. Finally, the solution was filtered by pouring it on another earthen pot where a bunch

Indigo in Bengal, Fig. 2 Indigo manufacturing (Source: Reid, The culture and manufacture of indigo)

of straws were placed as a filter. Five sers of indigo dye provided good color to six sers of cotton thread and $2\frac{1}{2}$ sers of silk.

Processing Under Foreign Technology

The imported technology had also four distinct stages of processing, though not necessarily bearing any resemblance to those under the indigenous technology. The stages were steeping, beating, boiling, and drying. All these processes were accommodated compactly in contemporary indigo firms.

Steeping: A large amount of water was required for steeping indigo plants. To get its regular supply, indigo works usually depended on wells or canals connected to perennial rivers. Water was first collected from those sources into a reservoir. The reservoir was made of brick walls, about 2–3 ft high, large in size (for exposing maximum water to the sun), and shallow in depth so that impurities might quickly subside. There was a cock in the reservoir enabling the flow of water to the steeping vat. Never was it fixed at the bottom, but a few inches above it, so that heavy impurities were prevented from flowing outward. The steeping vat was also brick built, about 3 ft high, with a diameter of

20 × 30 ft (Fig. 2). Its upper edge ran parallel to the cock of the reservoir for a smooth flow of water, whereby a brick-built channel was laid to connect them.

The main task in the steeping process was to extract the coloring particles from indigo plants that had been brought from the field. To accomplish this, the steepers put those plants in the steeping vat in a square structure so that the impregnated water could run off freely, and covered them with bamboos, weighted by beams across them, to keep them submerged in water. Finally, the reservoir was unpinned allowing water to flow in until the weeds were just covered (Fig. 3). In that state, they were left for 9–18 h for infusion and fermentation. The process was completed when the froth began to break with dull-looking bubbles appearing. The infusion was then drawn out of the weeds through a plug near the bottom of the steeping vat and collected into the beating vat. In the case of a well-fermented vat, the first burst after the opening of the pin should be bright orange. It would be reddish, when over fermented, and yellow otherwise.

Beating: The beating vat resembled the steeping vat in size and shape. Its upper edge was set at the foot of the latter so that the infusion could flow gently thereto (Figs. 2 and 3). The only difference was that its sides were curved

Indigo in Bengal, Fig. 3 Indigo vat (Source: Reid, The culture and manufacture of indigo)

inward at the top to prevent the liquor from splashing out during beating. There were three or more cocks, one above the other, by which clear water was gently drained away from the surface.

The task in this stage was to generate indigo granules by impregnating coloring particles, which were suspended in the water, with oxygen. To perform this task, 10–12 men were deployed in the beating vat. They stood in two rows of 5–6 each facing each other and beat the infusion as much as possible with wooden paddles or staves to mix air with it. During this operation, the liquor changed in color from bright to dark green, then to purple, and finally to dark purple blue, when the coloring particles were adequately impregnated with oxygen. When impregnation was done, the coloring particles became insoluble in water and united into a solid substance, which was called *facula* (*māl*). The grains were then allowed to settle at the bottom. Often, lime (*chunam*) water was added with it to prevent putrefaction afterward in the indigo. The beaters again came inside the vat and ran around several times to give the liquor a rotatory movement. They then quickly jumped out allowing the *facula*

to settle down again. The entire process took about 2–3 h.

Once the indigo granules settled at the bottom of the vat, the pins were opened up one after another in descending order so that the refuse water was gently run off, and the granules remained at the bottom. Those were then collected in buckets and poured into a reservoir under the boiler pump (Fig. 4).

Boiling: The boiler was a square, brick-built furnace with a large cauldron of iron (or copper) in the center. The *facula* that had already been put into the reservoir was pumped into the cauldron through two strainers, one at the mouth of the pump and the other over the cauldron (Fig. 4). The fire was then lit, and the *facula* was boiled for about 3 h. While boiling, it was stirred occasionally to prevent it from settling and sticking to the bottom. In this process, the *facula* was thickened, giving its particles a strong tendency to cohere.

Drying: After boiling, the moist indigo was poured on a draining table. It was made of transverse bars, surrounded by a ledge (Fig. 5), and covered with a sheet of cloth before beginning this processing. When the boiled indigo was put

Indigo in Bengal, Fig. 4 Pumping up of indigo (Source: Reid, The culture and manufacture of indigo)

Indigo in Bengal, Fig. 5 Indigo table (Source: Reid, The culture and manufacture of indigo)

on the table sheet, some facula ran out with the water. Those were at once pumped back into the sheet. The process continued until the water ran off perfectly clear.

The facula thus processed still contained some amount of water. To remove it, three more drying methods were followed. First, the table sheet on which the previous processing took place was

Indigo in Bengal,

Fig. 6 Indigo press and cake cutting machine
(Source: Reid, The culture and manufacture of indigo)

folded over the facula, and weights were put on to press it. This removed some amount of water from the matter. Second, the facula was then processed under screw presses. To do this, the dryer took up square boxes, which were perforated with holes on all sides, and lined with pressing cloth. The moist indigo was poured into those boxes and covered with the cloth on all sides so that when pressure was exerted on the matter, its aqueous content came out through the holes after it was filtered by the cloth. The boxes were then put under gentle pressure in the screw press (Fig. 6). The pressure was increased as the indigo hardened and assumed a shape of a bar. When adequately hardened, the bars were removed from the boxes and cut into cubes by a brass wire. Finally, the indigo cubes were brought in

the drying room and placed on the mats that were laid on shelves in tiers. The cubes were sprinkled with wood ashes to prevent flies from laying their eggs on them. When they were perfectly dried, they were cleaned with soft brushes and packed for dispatch.

The indigenous technology thus involved less sophistication than the foreign technology and should be less expensive. This was indeed confirmed in contemporary sources. Each maund of indigo dye evidently cost Rs. 16 under the former technology and Rs. 92 under the latter. Quality wise also, they were highly comparable. Montgomery Martin said, "Whether or not the European dyers have used judgement in rejecting the original and cheap manufacture of India, I cannot say . . . but there is no doubt that the dye produced

by the Indian kind is perfectly good. . . . [T]he Indian drug is . . . equally effectual, and probably easier wrought than the European. . .” (Martin, 1976, p. 986). But the Indian indigo was less productive so that a larger amount was required for a given end. Notwithstanding a lower unit cost, a higher total cost was thus implied. Moreover, it involved higher freight charges also, which was crucial for a distant market. It was, therefore, doubtful whether Bengal’s indigenous technology enjoyed comparative advantages in the European market.

- Japan was finding the length of a meridian by Japanese measure. Since Sino-Jesuit works had set zero longitude at Beijing, that of Japan had to be accurately measured so that, in predicting a solar eclipse, the Sino-Jesuit method could be employed for the Japanese longitude. After making over 2,000 measurements of latitude, Ino calculated the length of a meridian which agreed (within several tenths of a second of a degree) with the figure given in the Dutch translation of Lalande’s *Astronomie* which had been imported into Japan.

He did not excel in devising new methods or new theories in either astronomy or geodesy. While he was active, knowledge of Western astronomy was available through Dutch translations and Sino-Jesuit works and after, through the works of Lalande. But Ino had no knowledge of Dutch or dynamics and little understanding of astronomical theories. When calculating the length of the meridian, he considered the earth as a perfect sphere rather than a spheroid. Moreover, when observing the position of fixed stars, he did not take into account the effects of refraction, parallax, or nutation.

In his surveying, Ino did not use modern triangulation but relied upon the old traverse method. His mapmaking approach resembled the Sanson-Flamsteed method (it is presumed that his method was developed independently), which is appropriate only for small areas. Ino none the less used the method for an area as large as all of Japan. Despite Ino’s scientific failings, his map of Japan, based upon surveys covering the length and breadth of the land, has an important place in geographical history.

Ino Tadataka

Nakayama Shigeru

Ino Tadataka, 1745–1818, was a Japanese cartographer and an energetic field observer. A major astronomical and geodetic problem of the time in

Inoculation

Subhash Kak

The first reliable account of inoculation is found in the eighteenth-century reports by British doctors concerning the Indian treatment of smallpox. In the method, believed to have been discovered sometime before AD 1000 in India (Henderson & Moss, 1999), one deliberately inoculated, either into the skin or by nasal insufflation, scabs, or pustular material from lesions of patients. This resulted in an infection that was usually less severe than an infection acquired naturally. From India, the practice spread to China, western Asia, and Africa and finally, in the early eighteenth century, to Europe and North America.

It appears that the idea of inoculation derived from both *agada-tantra*, one of the eight branches of traditional Āyurveda (Indian medicine) that deals with poisons and toxins in small dosages, and from the application of specific concoctions to punctures in the skin for treatment of certain skin diseases (► *Suśruta Samhitā* in *Cikitsāsthāna* 9.10). The ► *Caraka Samhitā* speaks of how deadly poisons can be converted into excellent medicine and how two toxins can be antagonistic to each other. The *Samhitas* speak of organisms that circulate in the blood, mucus, and phlegm. In particular, the organisms in the blood that cause disease are said to be invisible.

The *Suśruta Samhitā*, Chap. 54 of *Uttaratantra* or *Kāyacikitsātantra* (General Medicine), suggests a treatment regimen that includes avoidance of fatty foods and sweets. In the *Nidānasthāna* (Diagnosis), Chap. 5, it is indicated that physical contact and sharing the same air can cause such diseases to spread. Later, in Chap. 13, there is mention of the eruptive boils of the disease *masūrikā*. It appears that originally it meant chicken pox, but by the twelfth century the term was also being used for smallpox, as in the case of the commentator Dalhana.

The best source concerning the Indian method of treatment of smallpox is a report by Dr. John Z. Holwell in 1767 for the College of Physicians in London. This report is an excellent source for understanding the mind of the Ayurvedic doctor of the eighteenth century.

Holwell says that inoculators are delegated for this service from the different Colleges of Bindoobund [Vrindavan], Eleabas [Allahabad], Banaras, &c. over all the distant provinces; dividing themselves into small parties, of three or four each, they plan their traveling circuits in such wise as to arrive at the places of their respective destination some weeks before the usual return of the disease (Holwell, 1971, pp. 150–151).

One would presume that they were Ayurvedic vaidyas or their assistants.

They inoculate indifferently on any part, but if left to their choice, they prefer the outside of the arm, midway between the wrist and the elbow, for the males; and the same between the elbow and the shoulder for the females. Previous to the operation the Operator takes a piece of cloth in his hand, (which becomes his perquisite if the family is opulent) and with it gives a dry friction upon the part intended for inoculation, for the space of 8 or 10 min, then with a small instrument he wounds, by many slight touches, about the compass of a silver groat, just making the smallest appearance of blood, then opening a linen double rag (which he always keeps in a cloth round his waist) takes from thence a small pledget of cotton charged with the variolous [smallpox] matter, which he moistens with two or three drops of the Ganges water, and applies it on the wound, fixing it on with a slight bandage, and ordering it to remain on for 6 h without being moved, then the bandage to be taken off, and the pledget to remain until it falls off itself. . . . *The cotton which he preserves in a double callico rag, is saturated with matter from the inoculated pustules of the preceding year, for they never inoculate with fresh matter, nor with matter from the disease caught in the natural way, however distinct and mild the species.*

The patient was to abstain from fish, milk, and ghee before and after inoculation for a period of

1 month. Holwell claimed that when the inoculation regime was strictly followed, it is next to a miracle to hear that it “failed in one in a million.” He added that since this practice of the East has been followed without variation, and with uniform success from the remotest known times, it is but justice to conclude, it must have been originally founded on the basis of rational principles and experiment.

This is how Holwell described the explanations offered to him by Ayurvedic vaidyas:

The *immediate* (or instant) cause of the smallpox exists in the mortal part of every human or *animal* form; that the *mediate* (or second) *acting* cause, which stirs up the first, and throws it into a state of fermentation, is multitudes of *imperceptible animalculae* [microorganisms] floating in the atmosphere; that these are the cause of all epidemical diseases, but more particularly of the smallpox; that they return at particular seasons in greater or lesser numbers... That these animalculae touch and adhere to every thing, in greater or lesser proportions, according to the nature of the surfaces they encounter; that they pass and repass in and out of the bodies of all animals in the act of respiration, without injury to themselves... smallpox is more or less epidemical, more mild or malignant, in proportion as the air is charged with the animalculae, and the quantity of them received with the food. (Holwell, 1767, pp. 155–156)

Holwell understood the idea behind inoculation in this manner:

That when once this *peculiar* ferment, which produces the smallpox, is raised in the blood, the *immediate* (*instant*) *cause* of the disease is totally expelled in the eruptions, or by other channels; and hence it is, that the blood is not susceptible of a second fermentation of the same kind.

In other words, he believed that when the disease in its natural form or when introduced in its weak form by the inoculation had run its course, the patient was safe. The difference between these two forms was that in its natural course it is often fatal, whereas when introduced through inoculation, it was only an inconvenience.

It is significant that the spread of disease was taken to be caused by the imperceptible animalculae (microorganisms). This old insight

of the *Āyurvedic Samhitās* was a forerunner to the germ theory of disease that arose in the nineteenth century.

Iron Pillar at Delhi

R. Balasubramaniam
Kanpur, India

The Delhi iron pillar (Fig. 1) is testimony to the high level of skill achieved by the ancient Indian ironsmiths in the extraction and processing of iron. Hadfield (1912) undertook the first systematic scientific study of the Delhi iron pillar. Results of scientific studies conducted in 1961 were summarized in a special issue of the *NML Technical Journal* (Vol. 5, 1963). A review of its corrosion resistance appeared in 1970 (Wranglen, 1970). While Anantharaman (1997) has reviewed the known scientific facts about the Delhi iron pillar, Balasubramaniam (2002, 2005) has compiled several new insights into the historical, scientific, and technical aspects of the Delhi iron pillar.

The history of the pillar is revealed in the die-struck three-stanza six-line Sanskrit inscription at a level of about 7 ft from the stone platform

(Balasubramaniam, 2000a). King *Chandra*, mentioned in the inscription as the royal donor of this *standard* for Vishnu, is probably identical with Chandragupta II Vikramaditya (AD 375–414), as was also suggested by the use of the name “*Chandra*” on that king’s Archer-Type gold

coins (Balasubramaniam). The original erection site of this pillar was Vishnupadagiri (literally “hill of the footprint of Vishnu”) as mentioned in the inscription. Vishnupadagiri is most probably identified with Udayagiri in central India, in the close vicinity of Besnagar, Vidisha, and Sanchi (Balasubramaniam; Dass, 2001). The astronomical significance of its erection site has been understood (Balasubramaniam & Dass, 2004). The pillar was positioned so that the early morning shadow of the pillar fell in the direction of one of the important bas-reliefs at Udayagiri, i.e., the *Anantaśāyin* Vishnu panel in Cave 13, in the period around the summer solstice. The *chakra* image that originally crowned the iron pillar capital additionally served to highlight its astronomical significance (Balasubramaniam, Dass, & Raven, 2004). The Delhi iron pillar was relocated to its current location in New Delhi in the courtyard of the Quwwat-ul-Islam mosque (near the Qutub Minar) around 1233 AD by Iltutmish (Balasubramaniam 2002; Dass 2001) (Fig. 2).

Iron Pillar at Delhi, Fig. 1 Delhi iron pillar located in the Quwwat-ul-Islam mosque in the Qutub Complex at New Delhi

Iron Pillar at Delhi, Fig. 2 Well-preserved Sanskrit inscription on the iron pillar. This is the oldest inscription on the pillar

Engineering Design

The current burial level of the pillar was not the original burial level of the pillar when it was erected at Udayagiri. Hammer-marked cavities are still visible on the surface of the pillar in the rough region just below the smooth surface-finish region (Fig. 3). The rough portion of the pillar

Iron Pillar at Delhi, Fig. 3 Hammer marked cavities are still visible on the surface of the pillar in the rough region. The rough region was originally buried under the ground when the pillar was located at Udayagiri

was originally buried in the ground and later left exposed outside when the iron pillar was relocated at Delhi around 1333 AD. Beglar, an assistant of Alexander Cunningham, constructed the stone platform around the base of the iron pillar in 1871.

A critical analysis of the dimensions of the main body of the pillar allows an appreciation of the pillar's symmetrical design (Balasubramaniam, 1997a). The rough surface occupies one-fourth (60U) and the smooth surface three-fourths (180U) of the pillar main body length, excluding the decorative top (Fig. 4). The decorative bell capital (Balasubramaniam, 1998a) is again a symmetrical object. A *chakra* (circular discus) image was originally located atop the capital (Balasubramaniam et al., 2004) and this would have been approximately 20U in

length thereby making the total length of the decorative top 60U (Fig. 5). Therefore, the depth of burial below ground level was equal to the height of the decorative capital, indicative of the engineering design of the pillar. The unit U is equal to 1 modern inch.

Iron of Delhi Pillar

Several analyses of the Delhi pillar iron's composition are available (Table 1). The variation in the published compositions and the high phosphorus content of the Delhi pillar iron must be noted. Compositional analysis near the surface regions of a sample from the iron pillar revealed that the composition of copper (0.05 %), nickel (0.05 %), manganese (0.07 %), and chromium (Nil) was uniform through several millimetres into the sample from the surface (Bardgett & Stanners, 1963).

The presence of phosphorus is crucial to the atmospheric corrosion resistance of the Delhi iron pillar. The Delhi pillar iron contains a relatively large amount of phosphorus compared to modern-day iron (produced in the blast furnaces). The relatively higher phosphorus content in ancient Indian irons is related to the kind of slag that was created in the extraction process (solid-state reduction). Lime was not added in the ancient Indian furnaces. The absence of calcium oxide in the slags leads to a lower efficiency for removal of phosphorus from the metal, which invariably resulted in higher phosphorus contents in ancient Indian irons. Thermodynamic analysis of phosphorus removal from iron in the absence of calcium oxide in the slag also provides the same answer (Kumar & Balasubramaniam, 2002).

Some aspects of the microstructure of the Delhi pillar iron are also known. All the available published microstructures have been described in Balasubramaniam (2003). It possesses a nonuniform grain structure and slag inclusions are irregularly distributed. Medium to coarse polyhedral grains of ferrite with slip bands were revealed in some grains near the surface. The surface regions were free from pearlite that

Iron Pillar at Delhi,
Fig. 4 Relative dimensions of the Delhi iron pillar. The unit U measures 1 modern inch

seemed to increase toward the interior. The absence of a uniform distribution of pearlite is indicative of the segregation of phosphorus because, in such areas of phosphorus segregation, carbon diffuses out and the material becomes poorer in carbon content. The interior portions were comparatively rich in carbon. Therefore, the Delhi pillar iron exhibits a wide variation in structure and this is also a characteristic feature of ancient Indian iron.

The pillar is a solid body with moderate mechanical strength (yield strength of 23.5 tons per sq. in., ultimate tensile strength of 23.9 tons per sq. in. and 5 % elongation (Ghosh, 1963)). The similarity of yield strength and ultimate tensile strength are indicative of the composite structure of the pillar iron. In fact, a cannonball fired at

the Delhi iron pillar in the eighteenth century (either by Nadir Shah in 1739 or Ghulam Qadir in 1787) failed to break the pillar.

Manufacturing Methodology

The pillar was manufactured using iron lumps and the method used to fuse the lumps together was forge welding. The individual iron lumps were extracted in bloomery furnaces. The likely manufacturing method has been deduced based on a critical analysis of various aspects concerning the manufacturing methodology like the hammering method, heating method, forging method, use of inserts, use of dies and ease of handling (Balasubramaniam, 1999a). The heated

Iron Pillar at Delhi, Fig. 5 The Delhi iron pillar decorative capital showing the discus image (*chakra*) that was originally located at the top of the capital

iron lumps were placed on the side surface of the pillar and hammered on to the same by the use of hand-held hammers (Fig. 6). The addition of metal would have been sideways with the pillar in the horizontal direction. The pillar’s vertical and horizontal movements would have been aided by handling clamps provided on the surface of the pillar, the protruding portion of which must have been chiseled away during the surface finishing operations. Visual proof for the presence of these clamps has been discussed in detail elsewhere (Balasubramaniam).

The decorative bell capital of the Delhi iron pillar has been described in great detail elsewhere (Balasubramaniam, 1998a). The decorative bell capital consists of seven distinct parts, excluding the circular disc that was originally atop the capital (Fig. 7). There are several evidences at the joints between members to indicate that lead solders were utilized for joining the pieces together (Balasubramaniam, 1998b, 1999b). The bottom-most part is the reeded bell structure, which has been manufactured by utilizing iron rods of uniform diameter. Atop this comes the slanted rod structure. The next three members are rounded structures, with the top one being only half rounded because when the pillar is viewed from the bottom, this part would appear curved when viewed in perspective from the bottom. A round disc comes above this and finally the box pedestal is placed on the top of the capital. The box capital contains holes that are empty at the four corners. The top of the pillar presently

**Iron Pillar at Delhi,**

Fig. 7 The (a) top and (b) bottom portions of the decorative bell capital

contains a hollow slot (Fig. 8), in which a *chakra* image was originally fit (Balasubramaniam et al., 2004). As regards the fitting methodology, the seven components of the capital were shrunk fit around a hollow cylinder, and this was joined to the main body of the pillar by means of a metallic insert (Balasubramaniam, 1998a).

Corrosion Resistance

Several theories that have been proposed to explain the superior corrosion resistance of the pillar can be broadly classified into two categories: the environmental and material theories. These theories have been critically reviewed

Iron Pillar at Delhi, Fig. 8 The top surface of the pillar capital presently contains a hollow slot

elsewhere (Balasubramaniam, 1997b, 2000b; Wranglen, 1970). The proponents of the environment theory state that the mild climate of Delhi is responsible for the corrosion resistance of the Delhi iron pillar, as the relative humidity at Delhi does not exceed 70 % for significant periods of time in the year. It is known that atmospheric rusting of iron is not significant for humidity levels less than 70 %. On the other hand, several investigators have stressed the importance of the material of construction as the primary cause for its corrosion resistance. The ideas proposed in this regard are the relatively pure composition of the iron used, the presence of phosphorus and absence of sulfur/manganese in the iron, its slag enveloped metal grain structure, passivity enhancement in the presence of slag particles and formation of phosphate film. Other theories to explain the corrosion resistance are also to be found in the literature. They include the mass metal effect, initial exposure to an alkaline and ammonical environment, residual stresses resulting from the surface finishing (hammering) operation, freedom from sulfur contamination both in the metal and in the air, presence of layers of cinder in the metal which do not allow corrosion to proceed beyond the layer (cinder theory) and surface coatings provided to the pillar after manufacture (treating the surface with steam and slag coating) and during use (coating with clarified butter).

That the material of construction may be the important factor in determining the corrosion

resistance of ancient Indian iron is attested by the presence of ancient massive iron objects located in areas where the relative humidity is high for significant periods in the year (for example, the iron beams in the Surya temple at Konarak in coastal Orissa (Graves, 1912) and the iron pillar at Kodachadri Hills on the western coast (Anantharaman, 1999). Moreover, a freshly exposed cut surface of the pillar acquires the color of the rest of the pillar in a relatively short period of time (Balasubramaniam, 2001), thereby implying that surface coatings were not intentionally applied.

Sanyal and Preston (1952) proposed that the large mass of the pillar implies a large heat capacity for the iron. In that case, the pillar would heat or cool faster than the surroundings. The role of the Delhi environment on the wetting and drying of the pillar has been mathematically modeled (Halder et al., 2004) and the benign role of the large mass of the pillar was noted.

Rust samples obtained from the region just below the decorative bell capital were characterized by X-ray diffraction (XRD), Fourier transform infrared (FTIR) spectroscopy, and Mössbauer spectroscopy (Balasubramaniam & Ramesh Kumar, 2000). The XRD analysis proved the existence of crystalline iron hydrogen phosphate hydrate, FTIR and Mössbauer spectroscopy proved the presence of magnetite and several oxyhydroxides in the amorphous form.

The process of protective film formation during alternate wetting and drying cycles of the Delhi iron pillar has been outlined (Balasubramaniam, 2000b) based on rust characterization results. Initially, the corrosion of the matrix is relatively fast due to the presence of second phase particles in the microstructure. The usual corrosion products that are observed in the case of mild steels exposed to atmosphere are generated: α -FeOOH (goethite), γ -FeOOH (lepidocrocite), $\text{Fe}_{3-x}\text{O}_4$ (magnetite) and X-ray amorphous matter. The initial enhanced corrosion of the matrix leads to the enrichment of phosphorus concentration at the metal-scale interface, which results in the formation of a compact layer of amorphous δ -FeOOH layer

next to the metal-scale interface. The formation of this layer confers the initial corrosion resistance to the pillar iron. Conversion of amorphous δ -FeOOH to nanocrystalline goethite is possible on longer exposure times (Yamashita, Miyuki, Matsuda, Nagano, & Misawa, 1994). The enrichment of phosphorus in rust continues with prolonged exposure as observed in P-containing weathering steels (Misawa, Asami, Hashimoto, & Shimodaira, 1974). Enrichment of phosphorus follows the mesoscopic variation of phosphorus in the matrix (Dillmann, Balasubramaniam, & Beranger, 2002). This enrichment should be responsible for the precipitation of the insoluble phosphate, identified by XRD. The formation of this phase at the metal-scale interface provides further corrosion resistance.

A kinetic model for the growth of rust on the Delhi iron pillar has been proposed (Balasubramaniam, 2002), based on the known nature and structure of the rust on the Delhi iron pillar and other corrosion resistant ancient Indian irons. According to this model, the initial fast rate of corrosion is followed by a period where the corrosion rate is reduced drastically. Growth rates have been roughly estimated for these two regions based on available Delhi iron pillar rust thickness measurements (Balasubramaniam).

The Delhi iron pillar is a marvel of ancient Indian metallurgical skills. I have explained the engineering design of the pillar followed by a description of the manufacturing methodology for the main body of the pillar. The characteristics of iron of the pillar and the possible reason for its high phosphorus content have been discussed. The theories of corrosion resistance of the pillar have been reviewed and the importance of the protective passive film mechanism has been highlighted. The nature of this protective passive film has been addressed based on a detailed characterization of its rust. The corrosion resistance of the Delhi iron pillar is due to both Delhi (with the environment providing alternate wetting and drying conditions) and iron (with its high phosphorus content conferring protection by the formation of a protective passive film).

Irrigation in Egypt

Claire Cookson-Hills

Queen's University, Kingston, ON, Canada

Irrigation in Egypt is dependent upon the Nile River and has been systematically utilized since the predynastic era. Egypt, surrounded by desert to the east, west, and south, and bordered by the Mediterranean in the north, receives little annual precipitation; the Nile therefore is the primary source of freshwater and the only source of water for agriculture. The annual flood of the Nile is caused by spring rains in Ethiopia washing down from the Ethiopian highlands and traveling north and west along the Blue Nile toward what is now Khartoum, where it joins the White Nile and flows north to the Mediterranean. Under the predynastic kings in the Nile Valley and the river Delta, the river's flooding provided natural inundation for crops. In his eloquent imagery, Alan Richards describes the Nile Valley like "the back of a leaf: the land slopes down gradually from the high land lying along the banks of the river... toward the desert" (Richards, 1982, p. 14). However, before 3100BCE, Egyptians were modifying the flood plain: building dykes and levees to divert the waters, creating intake canals to extend the cropped area, and modifying and making drainage channels.

Inundation, or basin, irrigation utilized the flood's waters. Under basin irrigation, the flood spilled over the river's banks and into shallow basins bounded by low walls, which held the water for approximately 40 days. At that point, the water was allowed to drain off the fields and either back into the Nile or into basins farther removed from the Nile banks. Since the floodwaters were full of Ethiopian silt, when the water

was either drained or allowed to infiltrate the soil, the silt was left behind and provided a layer of nutrient-rich fertilizer.

Around the time of the political unification of Egypt under the Pharaohs (c.3100BCE), basin irrigation was supplemented with the growth of crops year-round, specifically cereal grains (Bowman & Rogan, 1999, p. 5). Although the river floods in summer, it carries a large volume of water the rest of the year, mostly supplied by the White Nile. Egypt's warm and dry climate supports more than one crop each year, so farmers started growing multiple crops. First utilizing buckets and then hand-lifts (*shadufs*) after the Middle Kingdom, Egyptians lifted water from the river to irrigate their crops, gardens, and trees perennially. However, only those farms along the Nile Valley, beside the seven ancient branches in the Delta, or near a deep canal, could draw water year-round.

Ancient Egyptians made significant attempts to promote a large-scale, measureable, and regulated irrigated agriculture designed to improve, expand, and standardize the aforementioned irrigation system, with preeminence placed on controlling and measuring the flood (Butzer, 1976, 47). Nilometers measuring the height of the flood date back to around 3000 BCE. The first large-scale dam, the Sadd el-Kafara, was constructed in Lower Egypt around 2650 BCE. The largest dam in the world at the time, this structure was intended to control the Nile's floods but was destroyed shortly before its completion (Fahlbusch, 2009, p. 15; Mays, 2008, p. 472). From the Old Kingdom until 23BCE, the Fayum, a low-lying depression west of the river, was utilized for canal-irrigated agriculture. By 2300 BCE an existing canal into the Fayum had been transformed into a large-scale construction project connecting the Nile with the low-lying depression called Lake Moeris. The reservoir that this canal controlled high floods, regulated water in the winter, irrigated the surrounding area, and tripled the cropped area through irrigation and reclamation (Butzer, 1976, p. 47; Chanson, 2004).

In contrast to Pharaonic irrigation, which focused on flood control, the Macedonian

Ptolemaic Dynasty (332BCE–30BCE) emphasized canal irrigation (Mays, 2008, p. 473). The *saqiya* (waterwheel) and Archimedes Screw (screw pump) were introduced to Egypt by the second century BCE. These water-lifting devices were animal-powered and meant a drastic increase in the amount of water that could be poured onto the fields during the summer when the volume of water in the Nile was at its lowest ebb; the Ptolemies encouraged their incorporation (Bowman & Rogan, 1999, p. 2). A series of intake canals, dams, levees, and drainage canals were constructed to extend canal irrigation. More effective technology was paired with the large-scale planting of barley, winter wheat, and especially flax. With the newly introduced technology and the new crops, Egypt was able reliably to produce at least two crops per year (Bowman & Rogan, 1999, p. 2).

During the Roman (30BCE–641CE) and early Islamic (641–1171) periods, sugar, cotton, rice, and sorghum were introduced, but the Egyptian system of irrigated agriculture remained fairly consistent, producing up to three crops per year for both local use and export. Canal irrigation was further extended during the Roman and early medieval eras. Since these canals regularly silted up, canal maintenance was one of the key duties of the rulers and local lords under the Ayyubids (1174–1250) and Mamluks (1250–1517). The Ayyubids and Mamluks promoted sugar as the dominant cash crop, and refineries became an important secondary industry (Bowman & Rogan, 1999). However, the Egyptian population, which may have increased to as many as 14 million at the time of the Arab conquest, fell into a long decline, decreasing to approximately 3.25 million by 1798 (McCarthy, 1976). This falling population made canal irrigation difficult to sustain, and the total cropped area fell to 3.2 million acres in 1798.

After the Ottoman conquest of Egypt in 1517, Egypt again became a granary. Egypt grew rice, lentils, beans, wheat, and other agricultural foodstuffs for export to other parts of the Ottoman Empire (Richards, 1982, p. 7). Under the Ottoman regime, control over water usage devolved onto local governments which regulated village

water use instead of either the imperial government or individual water rights (Mikhail, 2011, pp. 21–22). Canal maintenance was part of the local institutional framework, including clearing the canal of silt after the yearly floods. Annual canal clearance was undertaken through the use of forced labor. However, under the Ottoman Empire, the Egyptian irrigation system was a continuation of the mixture of basins and canals extant since the Ptolemaic dynasty.

In 1805, Ottoman governor, Mehmet ‘Ali (r. 1805–1849) started to consolidate power by introducing a number of changes to irrigated agriculture with long-term consequences for Egypt. His government promoted the growth of long-staple cotton, a particularly thirsty summer crop. In order to extend cotton growth, the government built a new series of canals and built a large-scale barrage (the Delta Barrage, completed in 1862) near Cairo to raise the summer water level throughout the Egyptian Delta. Originally, this barrage suffered from structural problems, and as a result mechanical, coal-powered water pumps were introduced to replace the saqiya. In order to deal with the canals’ silting up, the system of forced labor became a “national imposition,” as peasants were compelled to work for months at a time away from their homes; Egyptian governments in the 1870s and early 1880s stopped this exploitative system of agricultural labor (Brown, 1994, pp. 125–126). During the American Civil War, as global demand for long-staple cotton skyrocketed, long-staple cotton became Egypt’s main export crop.

A British military force occupied the Ottoman colony in 1882. After the British occupation in 1882, Egyptian irrigation became increasingly focused on supplying summer water to the Delta to promote cotton growth. Repairing the Delta Barrage in the 1880s allowed agriculturalists to grow three crops per year. The British administrators instituted a number of modifications to the irrigation system which concentrated power in their own hands, and locked Egypt into a specific perennial irrigation system (Cookson-Hills, 2013). The British constructed the original dam at Aswan in 1902, which created a reservoir of 1 billion m³ in the southern Nile Valley.

This reservoir increased the amount of summer water to the cotton crops in the Delta by storing the floodwaters and releasing them later in the spring and summer when they were needed during the low-ebbed summer water. The Egyptian government also used the water to start converting the basins in Middle Egypt into canal-based irrigation. In response to ever-increasing water needs from a growing population (9.7 million people in 1897 and 11.3 million in 1907) and demand for long-staple cotton, Egypt raised the Aswan Dam in 1912 and again in 1933, increasing the size of the reservoir to 5.1 billion m³ (Collins, 1994, p. 69). In order to better regulate the extra water, the government built a series of other barrages: Asyut (1902), Zifta (1902), Esna (1906), Edfina (1951), and Nag Hammadi (1930). Scientific division and regulation of the Nile is a hallmark of twentieth-century Egyptian irrigation systems.

Since 1952, Egyptian nationalist governments have completed the transition from inundation irrigation to perennial irrigation. The Egyptian government finished construction on the Aswan High Dam in 1970. This dam gives Egypt “century-storage” – meaning that its 162 billion cubic meters of reservoir stores more than 1 year’s worth of water behind the dam. The dam itself cuts off the supply of replenishing silt from the Blue Nile and necessitates the heavy use of chemical fertilizers. The Aswan High Dam ended the annual flood; since 1964 the Nile in Egypt has become a series of irrigation canals completing control over the river and ending basin irrigation (Dumont, 2009). Although the Aswan High Dam extended the cropped area to almost 11 million acres, it has also been criticized for causing environmental problems such as desertification and soil salination (Bowman & Rogan, 1999, p. 2).

Irrigation in India and Sri Lanka

Claude Alvares

Assessments by historians of Asia's irrigation systems and irrigation-related civil engineering techniques have been based on the scantiest of historical or empirical data. Naturally, they have ranged from one extreme to the other. Of these, the one most easily recognized and debated was provided by Karl Wittfogel whose theories led to the idea of “hydraulic civilizations”.

A diametrically opposite assessment has been provided by some Indian historians who have concluded that there was no significant irrigation

technology in use at all. Symbolic of this view is R. Majumdar and H. C. Raychaudhuri's *An Advanced History of India*, in which the authors make a categorical statement on the “comparative absence of artificial irrigation” in eighteenth century India.

However both views – fairly representative of the historiographical terrain – have had to be revised considerably because of the emergence of new historical materials and investigations. These are reflected in new literature specifically devoted to the subject. Illustrative of these materials is the report of Alexander Walker, an English specialist who toured India in the eighteenth century. Walker produced an elaborate treatise on Indian agriculture in which he drew the conclusion that:

the practice of watering and irrigation is not peculiar to the husbandry of India, but it has probably been carried there to a greater extent, and more laborious ingenuity displayed in it than in any other country.

This display of ingenuity, however, is not restricted to eighteenth century India and has indeed found expression in a plethora of irrigation systems in Asia each designed to appropriate its own specific ecosystem potential. There is evidence of large-scale irrigation works in several Asian countries including China and Sri Lanka. The systems studied on the subcontinent include gigantic artificial lakes, large-scale and small-scale embankments, and diversion channels. They include schemes for taking water up a hill against gravity, elaborate canal distribution networks, innovations like the *khazans* on the west coast of India, where unmanned wooden sluice gates control the sway of salt and sweet water in low-lying paddy fields adjoining the coastal or tidal rivers, and storage tanks with a bewildering variety of names.

“The irrigation history of Indian has been studied only in fragments” (Sengupta, 1993). But even this admittedly fragmentary picture that is emerging is far more fascinating than the simplistic or impressionistic scenarios of Wittfogel or later historians like Raychaudhuri and Majumdar. The most fundamental aspect of irrigation technology and civil engineering works

to be noted is that almost all of them are related to monsoon precipitation in one way or another. Over 90 % of the annual runoff in the peninsular rivers and 80 % in the Himalayan rivers occur during the 4 months of the monsoon. Thus, unlike the case of temperate ecosystems, irrigation becomes extremely crucial: in the wet season which stretches approximately 4 months, in several places less, there can be too much precipitation over intense bursts. This is followed by a dry season during which there is no precipitation at all. The result is predictable: periods of excess water followed by drought.

In this context, the basic design of irrigation technology is intimately related to precipitation: how to save it, store it, and divert it, so that spatially it reaches areas where there is no water (diversion techniques) or temporally makes it available during the dry months (storage techniques). Thus, rain-fed rivers are diverted into channels, or river basins are interconnected. Or the rainfall is directly collected in huge storage facilities on the land.

If this is the scenario (and it is as valid today as it was in 3000 BCE), one would normally expect a much richer history of irrigation techniques in Asian conditions – where rice is a basic crop adapted to growing largely in water – than in any other part of the planet, particularly the temperate zones. It would also follow that the irrigation designs evolved for coping with such situations would not readily be available in other ecosystems. For this reason, it has taken some time for engineers and historians trained in other culture areas to appreciate their worth and function.

The irrigation experience of China is documented in Joseph Needham's *magnum opus*, *Science and Civilisation in China*, and will not concern us here. We shall restrict ourselves in this essay to a consideration of the irrigation and civil engineering techniques that arose in the Indian subcontinent including Sri Lanka and which were the result of a close interaction and adaptation between overall environmental situations and human ingenuity.

Irrigation Technologies

In the circumstances related above, it stands to reason that the primary design objective of irrigation engineers would be predominantly in the direction of a water storage system. The following listing is given by Shankari and Shah.

There were storage systems designed purely for drinking water: *nadi*, tanks, *bowari*, *jhalara*, and *pokhar*. Some were reserved only for human beings; others were for human beings and animals. These we shall ignore here.

The second category of storage technologies relates to irrigation, and there is considerable evidence of the spread of such technologies through the length and breadth of the subcontinent. Though the structures here were all designed for irrigation, they also provided other useful functions of soil conservation and ground water percolation and recharge.

Irrigation water stored in such storages was conveyed through two methods: first, under the force of gravity, or gravity irrigation, and second, through extractive or lift techniques or devices of some kind, including for instance the Persian wheel.

There were three main classes of such irrigation-related storage systems. The first comprised tank and pond irrigation systems. These in turn were of two types: *above surface* storage works, where a reservoir was created above the ground through a fairly long embankment. The corresponding structures were called *Keri*, *Eri*, *Cheruvu*, *Kalvai*, and *Kunta* in South India and *Ahar* in Bihar (northern areas). The second category involved *below surface* storage works, which included dug ponds from which water was lifted by some means manual or mechanical: *pokhar*, *talab*, *jhil*, *beel*, and *sagar*.

The second class of irrigation systems comprised land inundation systems: the land was flooded and saturated before cultivation and then drained off prior to planting (another term used is flood irrigation). These were primarily above surface types or referred to (in India) as submergence tanks. Important variations of these

are the *khadin* and the *johad* in Rajasthan and the *bundhies* of Madhya Pradesh.

The *bundhies* were built generally in a series and therefore captured every possible drop of rainwater that fell. If there were a surplus, a waste weir was provided. There was generally a sluice at the deepest part of the storage reservoir. A *stambh* or pillar would indicate the location of the sluice. Sluices could be of different types: pipe sluices or sluices made of masonry for the larger tanks. (Some sluices open, as in the *khazans*, with the pressure of the incoming tides and discharge water automatically when the tide has fallen; these are made from wood.) The crop which was grown in the *bundhies* after the water was drained did not require any irrigation until harvest.

The third class comprised in situ techniques through which storage facilities were created to retain precipitation and ground water infiltration. The difference between classes 2 and 3 was that in the former, cultivation followed drainage; in the latter it occurred simultaneously.

The sizes of these storage tanks varied and the tanks themselves were generally known from the command areas they irrigated: the smallest ones irrigated around 50 acres, the medium ones about 100, and the major ones 500 and above. The large tanks were clearly impressive in scale. The Veeranam Tank in Tamil Nadu has a bund (embankment) 16 km in length. The Gangaikonda Cholapuram tank, also in Tamil Nadu, was constructed by a Chola king from AD 1012 to 1044 and survives even today with a 25 km embankment.

The construction of tanks was a widely dispersed skill. To create a tank reservoir, an earthen embankment, usually curved, was erected in a concave form across the flow of water. The water was retained in the belly of the curve from where it was drawn and directed through channels to irrigate plots at lower levels through gravity irrigation. After the tank was emptied, the tank bed itself could be used temporarily for raising a crop utilizing residual moisture. Many of the tanks in an area were interlinked and functioned as parts of an integrated system. The tank

at the higher level released its surplus water as runoff to tanks at a lower level and the next in turn. These were called *chain tanks*. There were also tanks which were fed by canals from a river. Chain tanks were generally created in the upper reaches of the river basin and river-fed tanks in the lower reaches. Their construction would have required detailed cooperation among several communities in the region.

In Mysore in 1866 Major R. H. Sankey, Chief Engineer, wrote:

Of the 27,269 square miles covered by Mysore, nearly 60 % has, by the patient industry of its inhabitants been brought under the tank system. Unless under exceptional circumstances, none of the drainage of these 16,287 square miles is allowed to escape. To such an extent the principle of storage has been followed, that it would now require some ingenuity to discover a site within this great area suitable for a new tank.

The profusion of such tanks was not a feature of Karnataka alone. Experience was similar in Tamil Nadu, Goa, or Bihar. The area north of the Vindhya mountain range in middle India for instance had more than 8,000 submergence tanks. In one district of Rajasthan alone, there were more than 500 *khadins*.

In Sri Lanka, dry areas were populated with what are known as “tank villages”. “The 1-mile to an inch topographical maps of the island,” writes D. L. O. Mendis:

show nearly 15,000 of these, of which over 8,000 are in working condition today. Tradition has it that some 30,000 of these small tanks had been constructed down the ages and there is a reference in the chronicles to 20,000 in the ancient province alone in the twelfth century.

Water Conveyance

Apart from the storage works, the subcontinent witnessed the emergence of competent and impressive water conveyance systems designed to divert waters of rivers and flowing streams. Some diversions were accomplished without a check or embankment across the river; in such instances, the flood waters of the river were drained through a natural diversion. The *Kuhls*

or *Guls* in the Himalayan areas, the *dongs* of the Northeastern states, and the *pynes* of Bihar all reflect this feature.

The second category involved check dams as a basic feature: the river bed was first raised and the resulting raised water diverted into a channel as was the case with the *band-haras*. Some of these schemes were fairly small, like those in the hilly areas. Others could be extremely large-scale and it is the reports of the latter that probably gave Wittfogel material for his speculations. According to Major T. Greenway, these were works of “truly gigantic magnitude, vast embankments and drainage channels equal to ordinary English rivers in capacity.”

Historical Development of Irrigation Techniques

The interesting question that is now being asked is whether one can talk in terms of an evolution of irrigation technologies and civil engineering techniques from the earliest times to the present? The question is important in view of the fact that many of these storage systems, diversion channels, and embankments are largely intact and still in use. There are still parts of the country where Persian wheels are operated. Tanks and storage vessels are once again being made functional and weirs continue to be constructed.

The answer seems obvious: while more complex technological mechanisms did emerge as time passed, the earlier and the later techniques have continued to coexist. The only major new innovation seems to be the idea of dams; these are new in terms of function, since the generation of hydropower was not intended in earlier times. The idea of large dams, once considered the temples of modern India, has taken a severe beating in recent years. They are now considered unsuited to tropical ecosystems, since the reservoirs invariably lead to displacement of large numbers of people, submergence of forests, and destruction of wildlife, and in places like Sri Lanka, submergence of smaller functioning reservoirs.

This being said, it is possible still to identify certain periods as distinct historical events in a

possible history of irrigation and civil engineering on the subcontinent. There is archeological evidence of artificial irrigation from pre-Harappan and Harappan times (ca. 5500–3500 BCE): this took the form of a large number of wells. One well found had a brick lining going down 12 m. Post-Harappa, the major irrigation find is Inamgaon on the west coast of India where under the influence of the Jorwa culture (ca. 3400–3000 BCE), one finds evidence of a major diversion scheme reflected in a massive embankment 240 m by 2.2 m wide to divert the river into a channel. The channel itself was 200 m long and 4 m wide.

The first storage tanks in their rudimentary form appear around 2500 BCE – also in Sri Lanka – with the invention of iron tools. Hereafter, there are increasing references in literary works of both Sanskrit and Tamil up to the Gupta (AD 350) period. There are tank-related inscriptions which give details of tank construction, maintenance, sources of funds for maintenance, and so on. The word *eri* also comes into circulation by the seventh century as a term for tanks.

The *anicut* (weir) technique is probably older than the *eri* or tank. The most famous of the *anicuts*, the Kaveri Anicut on the river Kaveri, is linked to a Chola king of the second century AD. It involved a dam on the river Kaveri 300 m long and 12–18 m wide and 5 m deep. There is a dispute about the age of the *anicut*, since the *anicut* technique itself bears a strong resemblance to the Sri Lankan technique of massive stone dams and sluices, a technique which developed, according to Sri Lankan historian R. A. L. H. Gunawardene, only in the seventh century AD.

Sir Arthur Cotton paid eloquent testimony to the engineering talent involved in the large-scale irrigation works. He wrote:

There are a multitude of old native works in various parts of India. . . These are noble works, and show both boldness and engineering talent. They have stood for hundreds of years. . . it was from them that we learnt how to secure a foundation in loose sand of unmeasured depth. In fact, what we learnt from them made the difference between financial success and failure, for the Madras river irrigations

executed by our engineers have been from the first the greatest financial successes of any engineering works in the world, solely because we learnt from them. . . With this lesson about foundations, we built bridges, weirs, aqueducts, and every kind of hydraulic work. . . we are thus deeply indebted to the native engineers. . .

Social Arrangements/Religious Sanction

A significant feature of these irrigation works related to their construction and maintenance. Since water availability could be problematic with monsoon failure, those associated with the emergence of these works could gain religious merit for their deed. Though large systems were often sponsored by the state – to include kings, queens, local chieftains, *zamindars* (landowners) – village communities, temples, and even individuals are associated with their construction. Thus a public park in Pondicherry bears an inscription recording a tank built by a *dasi* – a temple dancer/courtesan – while another inscription in Karnataka (AD 1100) records a tank and shrine constructed by a village watchman.

All the major dynasties including the Mauryas (Sudarshan Lake near Kathiawar), the Cholas, the Hoysalas, and the Vijayanagar Kings and Muslim Sultans were associated with irrigation works. Of these, the most impressive schemes are associated with the Cholas. However, these kings depended upon a cadre of skilled hydraulic engineers. Dikshit records the performance of one such engineer in the fourteenth century:

The Kalludi (Gauribidanur taluk) inscription of 1388 AD is well known. According to it, when Vira Harihara Raya's son Sri Pratapa Bukkaraya was in Penugonda city in order that all the subjects might be in happiness – water being the life of the living beings – Bukkaraya in open court gave an order to the master of ten sciences, the hydraulic engineer (Jalasutra) Singayya Bhatta that he must bring the Henne (Pennar) river to Penugonda. Accordingly Singayya Bhatta conducted a channel to the Siruvara tank and gave the channel the name Pratapa Bukka Raya Mandalanda Kaluve.

The day-to-day operation and maintenance of both large and small works were mostly in the hands of local communities and of special

professionals like the *nirkattis* of Tamil Nadu. In many areas, production from certain lands was set aside specifically to meet the maintenance costs of tanks. During the installation of the colonial regime, these revenues were appropriated by the colonial power and consequently the maintenance of such irrigation works fell into bad times leading to declines in efficiency.

Irrigation in South America

Gray Graffam

Large-scale irrigation systems (canal irrigation) went hand-in-hand with the rise of cities and truly complex societies on the coast of Peru during pre-Hispanic times. Such systems delivered water to hundreds of hectares of potentially fertile land along a dry desert coast. Relatively late in prehistory, from 300 BCE onward, a number of well-known urban cultures (e.g., Moche, Lima)

undertook the construction and expansion of irrigation works, which supported dense populations. This process culminated around AD 1000 in the construction of exceptionally large and sophisticated works by the Chimú, including an intervalley canal of impressive proportions from the Río Chicama. These works made it possible for a population of some 25,000 to reside at the capital city of Chan Chan. Irrigation agriculture played a primary role in sustaining urban communities near the coast, where large irrigable plains of potentially fertile land were brought into production.

Similar irrigation systems in the Andean highlands are also of note. Some researchers, such as Michael Moseley, believe that irrigation agriculture developed here, as an extension of hunter-gatherer practices. Because of the steep slope, short canals would have been sufficient to water desired areas, and over the course of a millennium or more, a sophisticated irrigation technology developed. By AD 600, canal irrigation brought hundreds of hectares of otherwise unusable land into production in the Ayacucho valley of south-central Peru. These networks helped support a population of some 20,000 or more at the urban site of Huari, which is situated at an elevation of some 3,000 m, above any substantial acreage of arable land.

Other agricultural systems are also known for the Andes, and for elsewhere in South America. These include (a) sunken gardens on the desert coast, where plots of land were dug down to the water table and then planted, (b) terraces along the highland slopes, which served to retain moisture and enhance production, and (c) raised or drained fields along lake margins and in the Amazon basin, which served to reclaim inundated wetland. Aspects of irrigation technology theoretically come into play with each. Upland irrigation tends to create a higher water table downslope, which can make sunken fields possible in otherwise very dry areas. Slope irrigation can deliver a supply of water to terraced fields, and such systems are documented for the Inca. During the dry season, spring water can be run into the swales of raised field systems, which can allow for double cropping in some settings,

e.g., Lake Titicaca. Irrigation plays a role in other agricultural systems of the Andes. All of these agricultural systems were geared toward intensive production, as a means for dense human adaptation to the Andean environment.

In general, the construction and maintenance of irrigation systems are portrayed in the archaeological literature as a powerful force leading to the rise of civilization and urban life. This theory is based upon the view expressed by Karl Wittfogel, and subsequently anthropologists such as Julian Steward, that water management plays a key role in crystallizing political authority; it is also referred to as the "Hydraulic Hypothesis." According to this theory, highland peoples came to control a scarce resource of high value – water – which led to a hierarchical system for its management and distribution. Such a scenario is thought to have led inevitably to the formation of stratified society and subsequently state bureaucracy. Political power is seen as a direct outgrowth of the struggle for water, from which centralized authority and state-level government emerge. Not everyone agrees, and some scholars, such as Robert Adams, have argued forcefully that irrigation is the consequence of political power, rather than its cause.

The Peruvian data do not support the "Hydraulic Hypothesis" of civilization's emergence. A strong maritime economy typified subsistence strategy along the coast during preceramic times, and large agglutinated settlements that housed hundreds of people were built along the coast between 2500 and 1800 BCE, e.g., Huaca Prieta, El Paraiso, Río Seco, Playa Culebras, and others. There is an active debate on the role that crops, including maize, had in this developmental process, but it seems quite clear that irrigation agriculture played little part and certainly not to the scale of later times. According to Michael Moseley, the sociopolitical organization that accompanied these settlements was highly evolved, incorporating the management of labor mobilization (a form of taxation) on a regional basis. Irrigation agriculture took hold around 1800–900 BCE in the prehistoric sequence for Peruvian cultures. By this time, authority figures and labor taxation systems had

already emerged. Irrigation technology did not bring them about, but vice versa.

Still, the matter of irrigation's impact on society is a topic of central concern. For the north coast of Peru, it has been argued that irrigation technology went hand-in-hand with hierarchical social organization during late pre-Hispanic times. According to Patricia Netherly, water was a valuable commodity, and groups benefited from a hierarchically organized social structure, capable of resolving conflict when it occurred. Michael Moseley adds the perspective that large-scale irrigation projects were designed and engineered by rulers in these settings. Together both views provide a clear understanding of how irrigation was carried out, on the one hand through kinship organization, and on the other through government intervention in labor-intensive projects. Irrigation may not have given rise to civilization and urban life in the Andes, but it clearly evolved within the power structure of subsequent developments.

Today, systems of native irrigation management are under study, as are the impacts of modern attempts to improve them (Bolin, 1990; Mitchell, 1991). It is noted that highland communities often attempt to maintain their rights to water use and management, although in Peru such rights no longer exist in the legal sense. All water belongs to the Peruvian state, and there are national laws and regulations that govern its use. Highlanders, especially those who regard themselves as "Owners of the Water," fall into conflict with people in the lowland valleys. According to Bolin, there is a great need for agricultural and government agencies to investigate the indigenous patterns of water use, and the competition between and within villages for access to irrigation water. As revealed by Mitchell and Netherly, such patterns of water rights are likely to be deeply embedded within kinship organization and indigenous social structure.

Irrigation in the Islamic World

Lucie Bolens

From Andalusia to the Far East, from the Sudan to Afghanistan, irrigation in Islamic countries is the basis of all agriculture and the source of all life. After the Roman empire, the classical Islamic empires relied on the great cities like Damascus, Baghdad, Cairo, Cordoba, and Fez. In the countryside, all the small villages, made up of groups of rush huts or houses of stone, wood, or concrete were organized around a water source: a mountain fed by a living spring, a cistern of rain water, or wells bringing water up to the surface from deep beds. The Arabic word for water, *Māʾ*, is also the word for center. The water for religious ablutions at the center of the courtyard facing every mosque is the symbolic echo of a physical fact.

Islamic irrigation recovered pre-Islamic purviews while at the same time developing and expanding them. The historical record describes a vast network of canals from hot climatic zones to cold, rainy ones. The first were developed in the river valleys of semiarid and arid regions. The Nile, the Tigris and Euphrates, and the Guadalquivir have offered rural and urban communities

from earliest times both water and silt, a means of providing refreshment and nourishment.

Where no great rivers existed, human societies dug wells and prospected deep lying aquifer beds, in the south of the Arabian peninsula, in Yemen, and in Hadramawt, as well as in the Sudan. There, where the effects of Indian monsoons are often felt, a tropical agriculture (coffee trees, date palms, banana, and tamarind trees) served as a point of departure for those tropical plant species to Mediterranean regions.

Lastly, on the borders of agricultural zones stretched vast steppes with winter rainfalls varying from 50 to 150 mm per year, seminomadic lands which had been used for thousands of years. Animal husbandry and intensive agriculture at oasis sites have for centuries contributed to the economic base of Yemenites and Maghreb tribes. This association between seminomadic grazing and intensive irrigated agriculture is a distinctive characteristic of Islamic irrigation, a system of a complementary nature between field, pasture, and natural resources in the environment.

For classical Islam, written documentation is inseparable from the latest results of rural archeology; all of the *Kitāb-al-Filāḥat* (Books of Agriculture) – Maghrebian, Andalusian, Egyptian, Iraqi, Persian, or Yemenite – insist meticulously on the deployment of equipment and on the control of water. What are examined are the means of water distribution, following the season and the species being cultivated. A Tribunal of Waters looks at legal cases, and that of the Islamic writer Valence has lasted from the time of the Christian *Reconquista* in 1248 until today. Irrigation was linked to a social time, following necessities of nature but also following the social rank of the users.

In the current state of research, one of the oldest calendars of irrigation was found in the *Filāḥat al-Nabaṭiyyah* (Nabataean Agriculture, by Ibn Waḥshiyyah), which in the 1000s gave information on pre-Islamic Mesopotamia and Abbasidian Iraq. For western Islam, jurisprudence provided historians with precise details of daily life and ecological behavior, and explained the elements relating to the history of that environment, such as torrential rains in the autumn

and the spring, the shifting of waterholes, and complaints from the owners of cultivated estates which had been deprived of water from 1 day to another. The *fiqh* Islamic juris, had to regulate any unexpected events from case to case. The joint purchase of land and water, inherent to the *fiqh*, confronted the fact of the capriciousness of nature: the agrarian weather of microclimates really was the final law. In Islamic law ownership of land is always linked to ownership of waters.

Lastly, financial writings integrate the agrarian dependence on water into the framework of the whole political and social evolution of Islamic history. Irrigation is the crucial element of agriculture in Islamic lands.

The rains follow two dominant climatological patterns: one Mediterranean, the other tropical and subtropical. The Mediterranean basin, along with southern Africa and California, has the only climate which has rain in the winter and maximum heat in the summer. The vegetation there needs a hot, humid season in its tillage phase. In other respects, the torrential spring and autumn rains create a major risk for the thin, mountainous soil which is predominant in the Mediterranean basin. A negative quality can thus indeed have positive effects.

This link between the climate and the soil in Andalusia entailed three inseparable factors: an extremely fragile ecology at risk of erosion, a highly organized and detailed system of irrigation which was adapted to regional conditions, and a stable political and administrative system (except in time of war).

In certain historical cases, like that of Andalusia, in spite of the fluctuating tides of conquest and reconquest, there existed a true ecological pattern which lasted for several centuries and which served as a real ecological laboratory for eastern and western Islamic statutes, based on a high level of natural science, climatology, and botany. The extensive spread of theoretical and technical knowledge made of the Andalusian model a precedent which could be applied to all societies, ethnic, and religious differences aside, which were trying to understand the environment in its historical dimension.

It was water which governed the classification of land types. The rich agronomical and administrative literature of Arabic Islam divided cultivatable land into rainy land and irrigated land. The former were those lands which received enough winter rain to permit the cultivation of olive trees, grape vines, and citrus trees, the Mediterranean trilogy. Irrigated plantings used water stored in deep beds; the surface of the land was hot and irrigated and was worked in squares irrigated by ditches or *acequias*. The device which allowed the flowing of water into the ditches across fields, squares, or gardens was a wheel of variable dimension called a *noria*. More simply, on river banks and along the shore a system of scales and counterweights called *shaduf* was used.

The plan of irrigated water brought about a kind of intensive horticulture comparable to that achieved in the great Asiatic deltas. In the development of the countryside irrigation allowed plant species which became the basis of the popular diet – e.g., rice and legumes rich in protein – to become acclimated to the Muslim west. In Andalusia, sugar cane, rice, and cotton were cultivated.

In plateau regions (Meseta, Morocco, Iran) where aquifer beds were deep, the most profitable procedure was the traditional system of *qanats*. The *qanats* were deep drainage tunnels which directed water to springs or artesian wells. Some were over 16 km long, and their deep tunnel was dug from the outlet up to the mother-well. The gradient incline of the aquifer bed can range from almost zero to very steep. Well sites were marked and were used for ventilation and disposition of debris from land clearing. The science of the *qanats*, traditionally, was based on empirical knowledge and was passed down by gesture or through oral tradition. The earliest descriptions are Iranian. Later they were developed on the Castilian Meseta (Madrid) and in Morocco (in Marrakesh). Today, one can see them in Central America; they are the oil-qanats.

In between the canals of flowing water and the system of *qanats* the Islamic world watered its gardens and fields, its city courtyards and domestic patios, and its mosques, with water from wells

whose volume was increased through a process described by Ibn al-ʿAwwām in the *Kitāb al-Filāḥat* and in *Nabatean Agriculture*. Chapters relevant to finding the underground water level and sinking wells are followed by considerations on ways to increase the volume of water stored, ways to raise water from wells that are too deep, and ways to modify the taste of brackish or salty water.

The detailed observation of the earth or of its vegetation, in order to identify the presence of water, as well as the empirical nature of the investigation to sample the earth, in order to define various qualities of water, such as neutral, salty, or brackish and bitter, systematically mobilized the senses. Empiricism was able to bring about the creation of an irrigated, productive agriculture area. This success was built on the very controlled work of the *fellahs*, a political encouragement of individual appropriation, and on a high level of applied knowledge.

This multisecular, integrated system was the reason behind the development of numerous plant species crucial to the existence of civilization.

Irrigation Systems in Samarkand

Simone Mantellini

Department of History and Cultures, University of Bologna, Bologna, Italy

Dealing with the irrigation systems in the Samarkand oasis with a historical perspective means discussing both the canals watering the territory and the city supply. Commonly considered as the major center in the trade network along the Silk Road, since ancient times, the wealth of Maracanda (Samarkand in Greek sources) is based on a mixed economy, combining the irrigated agriculture in the floodplain with breeding and herding in the uncultivated steppe. However, like many other areas of Central Asia with low rainfall (ca. 350–400 mm/year) and arid environmental conditions, Samarkand and its territory could develop because of a complex irrigation network. The water of the Zeravshan, which is the third longest river of Central Asia, gives rise to the whole system. Springs and wells are less important and usually connected to the water supply in rural mountain areas.

Irrigation in Modern Times

The area of Samarkand is one of the most fertile in Central Asia, and today its cultivated surface covers approximately 3,500 sq. km (Fig. 1). As a result of the USSR's twentieth century policies, the most common crops are cotton, grapes, tobacco, and fruit trees. Crops extend equally on both sides of the floodplain alongside the two major historical canals: the Dargom in the south and the Bulungur in the north. Both branch off in

several minor canals that differ from each other in length, width, and flow rate. The Eski Angar, Yanghiaryk, and Siab-Karasu originate from the Dargom, supply the city and irrigate the southern part of the valley, whereas the Payaryk, Mirzaaryk, and Tuyatartar are the main canals diverted from the Bulungur in the northern half of the plain. 96.8 % of the water supplying the Samarkand region comes from the canals fed by the Zeravshan and the remaining 3.2 % from the piedmont seasonal streams locally known as *sai* (Alimov & Kadyrov, 1979, p. 147).

The Water Intake at Ravatkhodja-Varaghsar

Since the Zeravshan runs below the city of Samarkand and most of its territory, hydraulic control is required to make its water useful for irrigation and urban supply. Approaching Samarkand from the east, during his journey along the Zeravshan Valley in 1869, the Russian explorer A. P. Fedchenko (1870, p. 453) wrote:

Where the conglomerate ceases to prevail, there one finds the first of a system of very large canals, or 'aryks' dug for the irrigation of the southern parts of the valley. The lands here are much more elevated than those of the north ... but for the supply of water to the whole of the southern portion of the valley it has been necessary to divert streams at great elevations.

The whole system has its origin at the *Pervomayskaya plotina* (lit. May 1st Dam) in the village of Ravatkhodja, located on the Uzbek-Tajik border, 40 km to the southeast of Samarkand (Fig. 2). Here, at the outlet from the upper valley, the Zeravshan has high conglomerate banks and its width does not exceed 200 m. In 1921, a flood destroyed the first dam built in 1914–1916. After its reconstruction in 1927–1932 (Fig. 3), several stretches of the ancient Dargom were strengthened and cemented (Fig. 4). Two locks were then constructed at Akmachit and Kishrau to supply the major modern irrigation canals and three hydroelectric plants.
